LIGATION OF THE INFERIOR VENA CAVA OR ILIAC VEINS*

A Report of Thirty-Six Operations

WILLIAM R. MOSES, M.D.†

WASHINGTON, D. C.

THE first ligations of the inferior vena cava were performed by Kocher in 1883 and Billroth in 1885,¹ these procedures being the results of operative trauma and both being followed by a fatal outcome. The first successful ligation was performed by Bottini.² Two ligations of this type were performed in 1906 and a third in 1910 by Trendelenburg,^{3, 4} all for thrombophlebitis of the pelvic vein with septicemia, 1 patient recovering. Martens⁵ has reported 2 cases of ligation of the vena cava and 9 of the iliac vein for thrombophlebitic pyemia, 7 of the 11 patients surviving. Krotoski,⁶ summarizing the literature on the subject in 1937, collected 48 cases of ligation of the vena cava, performed by twenty-seven operators. Homans⁷ in 1944 reported 14 cases of surgical interruption of the iliac vein for venous occlusive disease of the lower extremities. In 1945, Kidd⁸ stated that successful ligation of the inferior vena cava for traumatic laceration had been accomplished in 9 cases. Shackelford and Whitehill⁹ have recently reported a ligation of the left common iliac vein for thrombophlebitis complicated by pulmonary emboli. Gaston and Folsom¹⁰ report 2 cases of ligation of the vena cava for bilateral thrombophlebitis with multiple pulmonary infarcts. Collins¹¹ performed ligation of the vena cava for pelvic thrombophlebitis in 8 patients with 1 death. Northway and Buxton¹² reported such a procedure in 10 cases — 3 patients having multiple emboli, 4 chronic edema of the legs with ulcerations, 2 swollen and painful legs without ulcers and 1 epigastric pain associated with phlebothrombosis. No deaths occurred in this series. Buxton and Collier¹³ reported 7 cases of ligation of the vena cava for bilateral disease of the leg vein and 1 of the iliac vein for unilateral disease. Kern and Berman¹⁴ and O'Neil¹⁵ have also added case reports of ligations of the vena cava.

Thus it may be seen that ligations of the great veins of the pelvis and the inferior vena cava, although not new procedures, are relatively infre-

quent in clinical application. In recent years, since such great emphasis has been placed on the prevention and treatment of pulmonary embolism, these procedures have become of mounting interest to the clinician and surgeon. Whether medical or surgical therapy will prove to be the more satisfactory solution for the problem probably depends on information to be gleaned from several more years of experience in the many centers interested. Meanwhile, it is imperative that attempts be made to obtain a critical analysis of the two modes of management, their criteria for diagnosis, the indications for whichever therapeutic methods are used by each school, the methods by which these measures are accomplished and the ultimate end-results. It was the aim of the investigation herein presented to provide the conclusions arrived at from the study of 36 cases of ligation of the iliac veins or the inferior vena cava operated on at the Gallinger Municipal Hospital.

The evaluation of any therapeutic approach to the problem of phlebothrombosis must of necessity await the clarification of the diagnosis of its presence. It has been suggested in a previous article¹⁶ that the clinical syndrome of edema, color changes, extensive tenderness, elevated white-cell count and red-cell sedimentation rate and local and systemic fever does not represent an early lesion of bland thrombosis, but rather an advanced state of the disease or a complicating thrombophlebitis. Operative findings in patients of this type demonstrate that the clot encountered in this phase is usually in a varying stage of fixation to the vein wall and has accordingly been rendered relatively innocuous. Phlebothrombosis resembles no other disease so closely as it does cancer in that the most significant phase of the disease occurs during the period when the diagnosis is the most obscure. In the same article, the clinical unreliability of the highly revered Homans's test was discussed and another method of examination was presented. While the aforementioned criteria for diagnosis continue to per-

*From the Surgical Service, Gallinger Municipal Hospital.

†Chief surgical officer, Gallinger Municipal Hospital; adjunct clinical professor of surgery, George Washington University.

vade the literature, it will be impossible to make a just appraisal of any therapeutic measures

The boundary zone between pure thrombophlebitis with relatively infrequent embolization and phlebothrombosis with its high risk of serious infarction is so broad and yet so vague that even surgical exposure of the clot is sometimes none too satisfactory in settling the issue. This handicap on the surgeon must rest still more heavily on the clinician who deliberately denies himself the certain knowledge of the nature of the disease under treatment. The fallibilities of phlebography were remarked on in the previous publication,¹⁶ and it is notable that this method of examination has suffered a sharp decline in popularity, even among some of its former advocates.¹⁷

SURGERY AGAINST ANTICOAGULANTS

Although it is not the primary intention of this article to discuss the relative merits of anticoagulants and surgical prevention and therapy of pulmonary emboli from peripheral phlebothrombosis, it may be proper to summarize our present attitude toward these two general methods.

In the first place, the anticoagulants, as represented by heparin and dicumarol, possess a threat of serious hemorrhage. We have witnessed at least 2 deaths that were due to their administration. One might well hesitate to increase deliberately a bleeding tendency in a patient whose lung is already oozing from an infarct or in a pregnant woman who has developed a venous thrombosis. Second, there seems to be good reason to believe that these drugs do not have the ability to affect the clots already formed and that their mode of action can only be on propagation of the existing clot. We have become familiar with the treachery of phlebothrombosis. How can one be assured, having made this diagnosis, that the process will not carry the threat of embolus even if halted exactly at the recognized level in the vein? The danger of the existing thrombus, whether great or small, remains for a period while the physician waits for the clot to adhere to the vein wall. Third, the decision concerning when therapy with dicumarol may be safely discontinued cannot be made on any criteria yet established. It is often necessary to reinstitute its use, and the decision for this appears to depend on the clinical signs of extension of the process, a source of danger in itself. Homans⁷ believes that it is impossible to determine by clinical examination whether the process has ceased to extend or is actually extending farther up the vein. Fourth, in contrast, the procedure of proximal venous ligation appears to be more certain. It has been repeatedly demonstrated by various observers to be a safe measure, and allows a prompt return to normal existence in the majority of cases, whereas the use of anticoagulants entails the loss of much time and expense and requires the most diligent care during therapy.

Lastly, the greatest objection to surgical management is apparently residual edema following ligation. In regard to this symptom following ligation of the iliac vein and vena cava, another section of this paper will cover its incidence and etiology.

INDICATIONS FOR LIGATION OF THE INFERIOR VENA CAVA

Fully realizing the inevitable state of flux in medical opinion concerning the entire problem of phlebothrombosis, and especially the management of both the local disease and pulmonary emboli, we have attempted to devise a working outline of the criteria on which the decision for ligation of the vena cava may be based. From our own experience, we have tentatively accepted the following indications: thrombophlebitis of the pelvic veins with pulmonary emboli, pulmonary embolus associated with prostatic tenderness of recent, or presumably recent, origin, especially with demonstration of deep tenderness along the anterolateral region of the rectum, reasonably conclusive evidence of pulmonary infarcts the source of which remains obscure despite diligent search, and venous occlusion of the lower extremities that would otherwise be treated by interruption of the femoral vein alone. The conditions governing the last are as follows: cellulitis or lymphangitis of the upper thigh, infections of the groin or the finding of enlarged and tender inguinal or femoral-triangle lymph nodes, recurrent emboli following bilateral ligation of the femoral veins, femoral phlebothrombosis with tense edema extending above the knee, the operative finding of adherent clot on exposure of the femoral vein, and acute thrombophlebitis extending into the upper thigh clinically, with the presence of pulmonary embolism.

In the prevention and therapy of pulmonary embolism, ligation of the inferior vena cava is related to interruption of the femoral vein not as a substitute but rather as a complement. The medical literature is replete with sizable case series proving that femoral ligations are safe, simple and responsible for a significant decline in the mortality from pulmonary embolism. There remain, however, certain conditions under which low ligations do not suffice and higher ligations than those of the femoral veins seem the procedures of choice. Thrombophlebitis of the pelvic veins with pulmonary emboli cannot be properly handled with any surgical intervention less radical than ligation of the vena cava. Krotoski⁸ prefers to ligate both iliac and ovarian veins under these circumstances, and ligates the inferior vena cava only if the process has advanced far up the iliac veins. This he accomplishes by celiotomy if a one-stage procedure is practicable or by a two-stage extraperitoneal approach if the condition of the patient is extremely poor. It is difficult to understand why the vena cava should not be ligated primarily rather than both

iliac veins Also, it is open to question whether ligation of the ovarian veins is necessary, especially since this procedure adds so much to the operation in comparison to the one-stage interruption of the vena cava No method completely blocks possible transit of emboli from the distal veins, but each method employed merely severs direct communication with the great veins, rendering this mode of transit so tortuous that advance becomes unlikely Ligation of the femoral veins for peripheral phlebotrombosis is based on this principle, and its effectiveness is beyond question We have considered ligation of the vena cava alone as adequate and simple, and the results in our few cases seem to support this contention Among those advocating interruption of the iliac vein and vena cava for embolizing pelvic thrombophlebitis are Bondy, Schottmueller and Beuttner (cited by Ochsner and DeBaKey¹⁸), Huggins,¹⁹ and Martens,⁵ who reported such a procedure in 11 cases, with 7 survivals, and Collins, Jones and Nelson,¹¹ who performed ligation of the vena cava, with 1 death in 8 cases

In a study of 189 fatal cases of pulmonary embolus, Henderson²⁰ found that prostatic-plexus thrombi were at fault in 18 cases (10 per cent) Although the diagnosis of prostatic-plexus thrombophlebitis is difficult to arrive at with certainty, it may be suspected in a patient exhibiting emboli, with an enlarged and tender gland and with tenderness and possibly induration extending along the anterolateral aspect of the rectum, especially developing as a recent finding in a patient already under observation in whom no other source of emboli can be detected Such criteria prevailing, ligation of the vena cava offers the obvious solution

In the series mentioned above, Henderson also found that 86 per cent of all emboli arose in tributaries of the inferior vena cava When there is reasonably conclusive evidence of pulmonary infarction, the source of which is obscure, ligation of the vena cava may be the procedure of selection rather than bilateral interruption of the femoral veins especially in patients whose occupation or social status makes persistent edema particularly undesirable Ligation of the vena cava is appreciably more inclusive in action Rössle²¹ found that in 10 per cent of his cases obscure emboli arose from the veins of the pelvis Bauer²² found that in 10 per cent of cases femoroiliac thrombophlebitis began in the deep pelvic veins Frykholm²³ states that in 16 per cent of his cases of thrombi they occurred in the iliac and pelvic veins

Not infrequently certain adverse circumstances prevail that contraindicate ligation of the femoral vein that would otherwise be performed In the presence of cellulitis or lymphangitis of the upper thigh or infections of the groin or the finding of enlarged and tender inguinal or femoral-triangle lymph nodes, often signifying latent regional infection, operations in this area result in a high incidence of

wound infection, sometimes of grave import When we have compromised with this judgment, acute thrombophlebitis has occasionally supervened on the ligated side, probably precipitated by manipulation of the femoral vein in a potentially septic field

In the earlier days of exploration of the femoral vein we lacked sufficient clinical experience to predict the operative findings from the results of clinical examination As these findings were more closely correlated, it became evident that tense edema extending above the knee does not occur from a simple phlebotrombosis confined below the inguinal ligament, and that when this type of edema does occur, the clot is too closely adherent to the wall of the femoral vein to permit effective and safe thrombectomy When these findings are encountered, and if a classical thrombophlebitis can be excluded, ligation of the vena cava is performed as a primary procedure It is worthy of emphasis that this clinical picture represents gross neglect, and its occurrence in a hospitalized patient is indefensible

On occasion, following bilateral interruption of the femoral veins, the embolic phenomenon continues and the problem of further management arises Under these circumstances, it is apparent that the true source of the emboli has been misjudged This source may be the profunda femoris vein on either or both sides if the superficial femoral veins have been ligated, or it may be the veins of the pelvic viscera The issue may be so clouded that accurate detection is impossible Re-entry of the incisions for higher ligation of the common femoral veins will result in edema of major and permanent degree Ligation of the vena cava provides the most satisfactory solution

Despite careful preoperative examination, there are times when the operator is taken aback by the operative discovery of adherent femoral clot, even though the bedside examination has revealed almost negligible clinical data In such a contingency a higher ligation is desirable, preferably without interference with the femoral vessels

When acute thrombophlebitis of the lower extremity, complicated by embolization, has invaded the upper thigh clinically, there is no surgical alternative to a high ligation

ILIAC-VEIN VERSUS VENA-CAVA LIGATION

During the earlier stages of our studies, we were inclined toward ligation of the iliac vein in the therapy of apparent unilateral disease not manageable by the femoral approach Homans,⁷ however, has since drawn attention to the likelihood of emboli from the apparently normal contralateral extremity Among others emphasizing the frequently bilateral nature of the disease are Frykholm,²³ Neumann,²⁴ Rössle²¹ and Gaston and Folsom¹⁰ It thus seemed that the rationale of iliac ligation was questionable, especially if combined with a femoral ligation on the

opposite side. Ligation of the vena cava is comparable to ligation of either iliac vein, requiring no more anesthesia, exposure, technical skill or time, indeed, it probably requires less of each of these factors than does ligation of the left iliac vein, which is short and lies under the aorta. For these reasons, we have entirely abandoned the iliac approach during the past year.

OPERATIVE PROCEDURE

Having used various types of incision in the exposure of these great veins, we have concluded that the following method is the simplest and most satisfactory one. It possesses the basic advantages of the McBurney incision for appendectomy, with no incidence of hernia, wound infection or denervation of the abdominal wall.

The incision, which is usually 9 to 10 cm in length, is placed 2 to 4 cm medial to the anterosuperior iliac spine on the right and parallel to the fibers of the external abdominal oblique muscle and fascia. This structure is divided in the line of its fibers, with exposure of the underlying internal oblique and transversalis muscles, which are spread widely to expose the peritoneum. This is swept medially, separating easily from the lateral and posterior abdominal walls and carrying with it the ureter and internal gonadal vessels. The inferior vena cava can be easily visualized. By blunt dissection it is carefully separated from the aorta on the left and the bodies of the lumbar vertebrae posteriorly. It is during this mobilization that extreme care must be taken to avoid tearing the lumbar veins, which enter the posterolateral aspect of the vena cava at intervals of 1 to 3 cm. Avulsion of one of these branches results in hemorrhage of the most trying nature. Following complete mobilization of the vein, it is under-run with a ligature carrier and fastened snugly with a nonabsorbable tie. The abdominal wall is closed in layers with interrupted nonabsorbable sutures.

Since the entire procedure is usually completed in ten to fifteen minutes, we have favored spinal anesthesia, utilizing procaine in doses of 40 to 50 mg. This has invariably proved adequate for the operation.

Complaints referable to the operative wound have been notably few and mild, as evidenced by an average of only 1.2 injections of opiate per patient during the postoperative period. There has been no case of ileus, as would be expected in view of the extraperitoneal approach. Any of these patients whose general condition permits can promptly become ambulatory.

There has been no example of shock developing during the procedure, with the exception of a patient who expired at the termination of the closure. Her death, which is discussed in a later section, is believed to have been due to another pulmonary embolus launched before the vena cava was ex-

posed. The amount of blood lost during the entire procedure, provided that the vena cava is carefully handled, does not exceed that lost during a simple appendectomy. In fact, an appendectomy through a McBurney incision seems to be an entirely comparable procedure as regards operative trauma. The mortality attending the procedure is, as Northway and Buxton¹² express it, the result of the disease rather than of the operation itself. O'Neil¹³ and Homans⁷ have suggested that spinal anesthesia, although preferable from the surgeon's viewpoint, may be hazardous owing to the flexed position assumed during the injection, and believe that general anesthesia may present less objection in this respect. It is also possible that the sympathetic paralysis attending spinal anesthesia may predispose to embolization by sudden relaxation of venous and arterial tone in the extremities. The relaxation of the abdominal muscles obtained by spinal anesthesia, however, is highly desirable. We used intercostal procaine block in only 1 patient (Case 9).

Postoperative edema. Collateral venous return following ligation of the inferior vena cava is much more adequate than one would suppose. O'Neil¹³ has divided the collateral pathways into three groups. In the superficial group are the superficial iliac circumflex and superficial epigastric veins connecting the saphenous system with the veins of the abdominal wall and superficial thoracic veins. In the deep group, the deep iliac circumflex, inferior epigastric and lumbar veins connect the external iliac to the internal mammary and ascending lumbar veins. The ascending lumbar trunks begin on either side of the sacral promontory and communicate with the sacral, common iliac, hypogastric and ilio-lumbar veins. As they ascend, they connect with the lumbar veins, the inferior vena cava and the right renal vein. The right lumbar trunk becomes the azygos vein, and the left the hemiazygos vein. To these groups may be added the vena cava-portal vein communications, particularly the retroperitoneal veins of Retzius, the para-umbilical plexus of Sappey and the superior-middle hemorrhoidal venous anastomosis. In light of these extensive side circuits it is readily seen that the collateral circulation after ligation is potentially enormous. O'Neil states that the edema of the legs following ligation of the vena cava is less than that following ligation of the femoral veins. Gaston and Folsom¹⁰ observed only minimal edema of one leg in 1 of their 2 cases. Kidd,⁸ in his report of 9 cases, found no case of persistent edema. Buxton and Collier¹³ found less edema after ligation of the vena cava in 7 cases than after the usual femoral-vein procedure. The patient reported by Kern and Ber-man¹⁴ had no edema up to five months after operation. Collins, Jones and Nelson¹¹ state that the venous pressure returns to normal in a short time after ligation. Whittenberger and Huggins¹⁵ regard edema as unlikely when the vena cava is ligated.

below the renal veins. Pleasants²⁶ found that sudden occlusion of the lower vena cava failed to produce edema unless the iliac veins were also blocked. Northway and Buxton,¹² however, estimate twelve months as the average time required before venous pressure returns to normal and found that all their 10 patients had mild, but no severe, edema. Two required ligations of varicose veins, and 1 a ligation of distended thoracoepigastric veins after ligation of the vena cava. Homans,⁷ recommending ligation of the vena cava if the thrombosis is bilateral and extends to the inguinal ligaments, states his belief that the venous return is poorer than that following iliac interruption because of the loss of the transpelvic venous shunt. Our own findings can be summarized by stating that whenever edema has followed ligation of the vena cava or iliac veins, there has been unequivocal evidence of either persistence or recurrence of the disease process.

DISCUSSION OF CASES

In this series are included thirty-six ligations of the inferior vena cava or iliac veins, — 21 of the former and 15 of the latter, most of the latter having been performed during the early studies. These procedures were done on a total of 35 patients, there being 1 patient who was subjected to ligation both of the left common iliac vein and of the vena cava. During the past year, for reasons previously outlined, we have abandoned the iliac approach. Under our present tentative indications, all these 15 patients would have been subjected to ligation of the vena cava.

The conditions necessitating these operations were as follows: recurrent emboli following bilateral interruption of the femoral veins (2 cases, 1 death), thrombophlebitis of the pelvic veins, with infarctions (2 cases, 1 death), pulmonary emboli associated with venous clot fixed to the wall of the femoral vein and extending into the iliac vein (17 cases, 9 deaths), venous clot, adherent to the femoral vein and extending into the iliac vein, without emboli (11 cases, 1 death), phlebitis of the prostatic veins, with emboli (1 case, patient living), pulmonary emboli associated with venous occlusion of the lower extremities, usually treated by femoral interruption, contraindicated by disease in the groin (2 cases, 1 death).

The following are brief abstracts of the cases in which death occurred during the postoperative period.

CASE 1 (C10449) A 46-year-old Negress was admitted with and treated for bilateral ovarian abscesses. She pursued a downhill course and developed pelvic thrombophlebitis with multiple pulmonary infarcts. Since her condition was critical, the vena cava was ligated under procaine spinal anesthesia. Sudden shock occurred just as the vein was exposed, the right internal iliac vein clotted, and the patient died as skin closure was being performed, 8 minutes after the operation had been begun. Permission for autopsy was refused. It is believed that the patient had embolus in the operating room.

CASE 2 (C6869) A 51-year-old Negress was admitted in congestive failure due to hypertensive heart disease. She developed phlebotrombosis of the femoroiliac vein with multiple infarcts. The vena cava was ligated 15 days after admission, but the patient died 10 days later. Autopsy showed multiple infarcts, cardiac dilatation and thrombosis of the right iliac vein and lower vena cava.

CASE 3 (C465) A 63-year-old Negress was admitted with hypertensive heart disease. She developed left phlebotrombosis and multiple infarcts. The left femoral and left iliac veins each contained an adherent clot. The vena cava was ligated, but death occurred 9 days later. The autopsy findings were the same as those in the previous case, together with a dissecting aneurysm of the aorta and bacterial endocarditis.

CASE 4 (B99304) A 63-year-old man was admitted with suspected pulmonary infarct or pneumonia. He had an infected toe, enlarged femoral and inguinal lymph nodes and a +++ edema of the right leg and foot. The vena cava was ligated on the day of admission, but the patient died 7 days later. Permission for autopsy was refused.

CASE 5 (B96267) A 72-year-old woman was admitted 1 month after mastectomy for carcinoma of the breast. Swelling of the right leg had developed insidiously at home. There was a +++ edema of the entire right lower extremity. The vena cava was ligated, but the patient died 9 days later. Autopsy revealed thrombosis of the right iliofemoral vein, pulmonary edema and bronchopneumonia.

CASE 6 (B93969) A 67-year-old Negro was admitted with multiple infarcts following amputation of a leg for arteriosclerotic gangrene despite prophylactic ligation of the femoral veins. The vena cava was ligated, but the patient died the next day. Permission for autopsy was refused.

CASE 7 (B94818) A 53-year-old Negro was admitted with hypertensive heart disease and pulmonary infarct. The left femoral vein contained an adherent clot. The left iliac vein was ligated. The infarcts continued, and the vena cava was ligated 4 days later, but death occurred 8 days later. No autopsy was performed.

CASE 8 (B94008) A 54-year-old Negress was admitted with diabetes, infarct and minimal leg signs. Each femoral vein contained an adherent clot. The vena cava was ligated, but the patient died 28 days later after a septic course. No autopsy was performed.

CASE 9 (C17519) A 67-year-old Negress, while under medical investigation for probable carcinoma of the colon, developed insidious edema of the left leg. There was a +++ edema, sudden syncope, cyanosis, dyspnea and semistupor. The vena cava was ligated under intercostal block, but the patient died 3 days later. Permission for autopsy was refused.

CASE 10 (B87828) A 40-year-old Negress was admitted with multiple pulmonary infarcts and thrombophlebitis of the right femoroiliac vein. The right common iliac vein was ligated, but death occurred 20 days later. Autopsy showed the above, as well as thrombosis of the cerebral artery.

CASE 11 (B94942) A 24-year-old Negress was admitted with far advanced bilateral pulmonary tuberculosis, Pott's disease, spinal fusion, a draining sinus over the site of fusion possible pulmonary embolus, and phlebotrombosis of the right femoral and iliac veins. The common iliac vein was ligated. The patient died of tuberculosis 14 months later. No autopsy was performed.

CASE 12 (C6161) A 54-year-old Negress was admitted with thrombophlebitis of the left femoroiliac vein and multiple infarcts. The left common iliac vein was ligated, but the patient died 6 days later. Autopsy revealed thrombophlebitis of the common iliac vein and multiple pulmonary infarcts.

CASE 13 (B94968) A 59-year-old man admitted with hypertensive heart disease developed thrombophlebitis of the right femoroiliac vein, possible multiple infarcts and possible bronchopneumonia. The femoral and iliac veins were thrombosed. The iliac vein was ligated, but the patient died 8 days later. Permission for autopsy was refused.

It is manifestly impossible to evaluate the degree, if any, to which surgery contributed to the death of any of these patients. Their preoperative condi-

tion, as in most of those surviving, varied from extremely poor to critical, most of them having serious cardiac or pulmonary lesions or combinations of the two. One is perched on the horns of a dilemma

The gamble is usually lost in patients as critically ill as those in the cases summarized above. The gloomy picture is considerably brightened, however, when one witnesses the dramatic improvement made by

TABLE 1 *Data on 22 Patients Surviving Iliac-Vein or Vena-Cava Ligation*

CASE No	HOSPITAL No	SEX	AGE yr	RACE	INFARCTS	PREOPERATIVE EDEMA	LIGATION	POST OPERATIVE EDEMA	REMARKS
14	C15614	M	48	W	Multiple	+	(bilateral) Vena caval	0	Patient with hypertensive heart disease developed multiple infarcts and his condition became critical. There were no leg signs, but there were acute prostatic swelling and tenderness and induration of anterolateral area of rectum.
15	C13401	M	61	N	One	+++	(right) Right iliac	+	(right) Patient had insidious swelling of right leg for 2 wk and chest pain and hemoptysis for 6 hr before entry. Right common iliac vein was thrombosed.
16	C12902	F	48	N	None	++	(bilateral) Vena caval	++	(bilateral) Patient had insidious bilateral swelling of legs 5 wk after combined resection of rectum. The leg signs were positive and the iliac veins thrombosed.
17	C9704	M	52	W	None	++++	(right) Vena caval	0	Patient had insidious swelling of right leg for 3 wk. Right iliac vein was plugged. Patient readmitted for right thrombophlebitis.
18	C8425	F	66	W	One	+++	(right) Vena caval	0	Patient had had hip nailing 4 mo previously, with nonunion. Following a massive, nearly fatal embolus right leg was swollen.
19	C8234	F	37	N	One	++	(left) Vena caval	+	(left) Patient had a massive embolus following an operation for a fibroid uterus and an ovarian abscess. There was swelling of the left calf and the left femoral vein was plugged.
20	C7296	F	58	W	None	++++	(right) Vena caval	0	Patient had insidious swelling of right leg and thigh during preparation for a gastrectomy. The right iliac vein was thrombosed. Cava later resected.
21	B98021	M	17	N	Questionable	++	(left) Vena caval	0	Patient admitted with questionable pneumonia or infarct. There was acute swelling of the left foot and calf and the left femoral and iliac veins were thrombosed.
22	B93383	M	63	N	Multiple	+++	(left) Vena caval	+	(left) Patient had cellulitis of left leg and thigh with repeated infarcts.
23	B93511	F	44	N	Multiple	0	Vena caval	0	The infarcts accompanied a salpingitis and the patient's condition was critical preoperatively.
24	C11665	M	60	N	None	+++	(right) Vena caval	0	(2 mo) Patient had insidious edema of right leg and thigh 11 days after gastrectomy.
25	C20025	F	42	W	None	0	Vena caval	0	(3 wk) Lumbar sympathectomy was performed for thrombosis of right femoral artery. The right iliac vein was also thrombosed, and the cava was ligated at the same operation.
26	B88180	F	40	N	None	++	(left) Left iliac	+	(left) Patient had thrombophlebitis of left femoral and iliac veins.
27	B90940	M	30	W	None	+++	(right) Right iliac	++	(right) Patient had recurrent femoral phlebitis with chronic edema.
28	B92500	F	26	N	One	+++	(left) Left iliac	++	(left) Patient had postabortal thrombophlebitis of left femoral and iliac veins.
29	B95416	F	68	W	None	+++	(left) Left iliac	0	Left femoroiliac phlebothrombosis developed following the nailing of a fracture of the neck of the left femur.
30	C5252	F	71	C	One	++	(left) Left iliac	0	Patient had insidious swelling of left leg following fracture of the right tibia. There was an embolus after bilateral femoral ligation.
31	B87907	F	44	C	Two	++++	(right) Right iliac	0	Patient had right femoroiliac phlebothrombosis. A left femoral ligation was also performed.
32	B85462	F	66	W	One	+++	(left) Left iliac	0	A left phlebothrombosis during the course of a meningococcal meningitis.
33	B85427	F	69	W	Multiple	+++	(right) Left iliac	++	(right) Patient had a phlebothrombosis of the right leg. The left femoral vein was filled with an adherent clot. A right femoral ligation was also performed.
34	B81965	F	36	W	None	+++	(right) Right iliac	0	An insidious swelling of the right leg followed a thoracic empyema. The right femoral vein was filled with adherent clot.
35	B90320	F	71	W	None	+++	(right) Right iliac	+	(left) An intertrochanteric fracture of the left femur was followed by insidious swelling of the right leg. The right femoral vein was filled with adherent clot. Right and left femoral ligations were also performed.

when he witnesses the sapping of a patient's cardiac and pulmonary reserve from repeated infarctions not amenable to interruption of the femoral vein

other patients who appear as seriously ill. The essential data accumulated on those who survived are presented in Table 1.

SUMMARY

The history of operative interruption of the inferior vena is reviewed

A tentative list of the criteria for ligation of the vena cava is presented and discussed

The reasons for the recent abandonment of the iliac approach are enumerated

The operative technic of ligation of the vena cava is described, and the incidence and etiology of post-operative edema of the extremities are discussed

Abstracts of the case histories of the 13 patients who died following operation and the essential data on the 22 who survived are presented

NEUROPSYCHIATRY IN THE EUROPEAN THEATER OF OPERATIONS

COLONEL LLOYD J THOMPSON, M C, A U S *

THE best way to present this subject is to do it chronologically, discussing various topics just as they developed in the theater Neuropsychiatric services in the European theater were at all times a part of the general medical services For example, in the Division of Professional Services of the Office of the Chief Surgeon, the senior consultant of neuropsychiatry functioned under the chief consultant in medicine Also, in all hospitals the Neuropsychiatry Section was part of the division of the medical service The term "neuropsychiatry" was maintained in keeping with the practice of not separating neurology and psychiatry except for those aspects of neurology that fell within the neurosurgical services

The year 1942 was a ground-laying period in which the foreign theater had comparatively few troops, most of whom were in North Ireland By the end of the year six general hospitals were in operation and all psychiatric services were centered in these hospitals None of these hospitals, however, had wards that were specifically designed for neuropsychiatry Accordingly, plans were drawn so that one medical ward in each general hospital would be converted into a ward for neuropsychiatric patients This plan was adopted for all the general

hospitals that were being built in England for the United States Army The policy of maintaining inpatient, outpatient, rehabilitation and consultation neuropsychiatric services in all station and general hospitals was adopted quite early As the number of general hospitals increased, personnel problems, especially so far as neuropsychiatrists were concerned, developed here and there, and at times the Neuropsychiatric Section was headed by a medical officer who had had little experience in psychiatry This was corrected as soon as possible, and for the most part the services in general and station hospitals were adequately handled

To keep neuropsychiatry intimately related to and part of general medicine was considered extremely important This was in keeping with the definite trend in civilian as well as military medical practice Steps to establish entirely separate hospital units for neuropsychiatry were taken with reluctance and caution, regardless of the experience in the last war and the experience of the British in this war It appeared to be a backward step, but since the American general-hospital installations had only improvised facilities at the time for psychotic patients, it was evident that special provision had to be made Future developments revealed that for the nonpsychotic patient there were many advantages in a separate mental-rehabilita-

*Professor of psychiatry Bowman Gray School of Medicine of Wake Forest College Winston-Salem North Carolina (on leave of absence)

tion unit. In a neurosis or mental-rehabilitation hospital where the patient did not come in contact with physically sick or wounded soldiers the atmosphere of recovery and return to duty could be created and carried on from admission until final disposition. Although the general and station hospitals carried out the same technics of treatment and rehabilitation, the total atmosphere could never be captured. Few of the general hospitals approached the return-to-duty rate of the special neuropsychiatric hospitals, and the latter usually received only the patients whom the general hospitals had been unable to return to duty. Fortunately, the special neuropsychiatric hospitals were large enough to include medical, surgical, x-ray, laboratory and dental services that were at least equal to those found in many other hospitals.

Before the arrival of the senior consultant in neuropsychiatry, steps had been taken to procure a British mental hospital at Exeter, with the object of having a holding place for psychotic patients. This hospital was opened for patients on January 23, 1943. The 36th Station hospital, a special neuropsychiatric unit under the command of Colonel Ernest H. Parsons, arrived just in time to start this function. This was a 250-bed unit, and the installation had room for 350 patients.

Within a month a special rehabilitation section, called the Training Company, was established. It was organized on a strictly military basis, with a captain from the Air Corps, who was a patient, as commanding officer. The wards were turned into barracks and the entire program throughout the day was on a military basis. The daily schedule included reveille, setting-up exercises, drill, military training, athletics and assignment of work details. There was a great variety of work assignment, such as repair of buildings and roads and the erection of garage and post exchange buildings. All occupational therapy was concerned with constructive activities that improved the installation. Group discussions and information and education activities were included in the program. Without too much difficulty a return-to-duty atmosphere was created. The results were soon evident in hospital statistics with a return-to-duty rate for nonpsychotic patients of over 50 per cent.

In March, 1943, plans were begun to have a separate and larger neurosis hospital. This was accomplished by the following November, and the 312th Station Hospital was made over into a neuropsychiatric unit. The plan of function that had been evolved at the 36th Station Hospital was adopted. After the initial work-up of each case, with a decision as to type of treatment, the patient spent between ten days and two weeks in the treatment section. Following this he was transferred to the training or rehabilitation wing, which was the needed step between hospital care and duty. At this hospital the return-to-duty rate averaged 80

per cent. It must be kept in mind that patients were received only after general hospitals had failed to return them to duty.

As a result of this experience and for various other reasons, it was decided that a similar neuropsychiatric unit should be formed to function on the Continent just in the rear of the Army. Accordingly, the 130th General Hospital, which arrived on August 1, 1944, was remade into a neuropsychiatric unit. As such it arrived in France on September 4, 1944, but because of loss of equipment was not able to start functioning until November 17. It was located at Ciney, Belgium. At first it was in a good position to receive all the neuropsychiatric patients coming out of the First and Ninth Armies, but because of an overflow of medical and surgical cases from the Liège area it did not begin to function as a neuropsychiatric unit until December 1. Then came the Battle of the Bulge, and by December 20 it was evident that this hospital would be in the center of the German drive. The commanding officer, Colonel Parsons, evacuated most of the patients and his staff, remaining behind with a few volunteers to care for nontransportable patients. Just before Christmas, the hospital was practically surrounded and the main road of escape was cut. German officers requested that adequate care be given wounded Germans, and this was done. Before the end of the year the German retreat had started, and by January 2, 1945, it was possible to bring back the staff and the hospital continued to function. At that time it was in front of the aid stations, but it soon became a field hospital, then a clearing station and later an evacuation hospital. During the latter part of January and during February it had to function as a regular station hospital. By the time its primary function as a neuropsychiatric unit was resumed the armies were beyond the Rhine and evacuation was being done almost entirely by air. This meant that all patients were flown beyond the area in which this hospital was located, the majority coming to Paris. During the periods that this hospital was able to function as a neuropsychiatric unit it was able to return 90 per cent of its patients to duty.

A similar unit, the 51st Station Hospital, came to the Continent from North Africa and served the Third and Seventh Armies. This hospital met the same fate that befell the 130th General Hospital. During the Battle of the Bulge it was necessary for it to do surgical work. Also, in the spring of 1944 patients were being flown from beyond the Rhine to the Paris area. This hospital when fully functioning as a neuropsychiatric unit also returned 90 per cent of its patients to duty. Before either of these hospitals could be moved forward, V-E Day came and the care of neuropsychiatric patients was centered in a general hospital in Paris.

Before leaving the subject of special neuropsychiatric units, mention should be made of the School of

Neuropsychiatry, which was really a part of the neuropsychiatric units. This was first opened in April, 1943, at the 36th Station Hospital under the direction of Lieutenant Colonel Jackson Thomas. At first neuropsychiatrists coming into the theater with general and station hospitals were given a one-month course. Along with this went courses for nurses and enlisted men working in neuropsychiatric sections of general and station hospitals. Also, during the summer of 1943, several courses, each lasting one week, were given for medical officers of ground force units. In September, 1943, Colonel Thomas was recalled to the Zone of the Interior, and it was not until late in the year that Major Howard Fabing arrived to take his place. The school was then moved to the 312th Station Hospital and practically all the instruction was given to front-line medical officers. Weekly classes were held for these men until the middle of July, 1944. As a part of the services to ground-force units it was necessary to train approximately 15 division psychiatrists. In addition to this, neuropsychiatrists, nurses and enlisted men from evacuation hospitals and other forward units were given definite courses of instruction. Approximately 700 medical officers who later worked in aid collecting or clearing stations were given the one-week course in what was called "first-aid psychiatry." The total number of persons attending this school was approximately 1200. A feature of the school was a weekly tent show in which conditions at the front were simulated and various syndromes of combat exhaustion were acted out and treated.

Before turning to the psychiatric services in the Army, mention should be made of the fact that there were psychiatric services in the two large reinforcement depots that handled patients going back to duty from hospitals. Also, the disciplinary training centers had psychiatric services. Mention should also be made of the Recovery Center, although there was no psychiatrist there. This was a training unit, with rather strict military discipline for the unwilling soldier. Trainees were carefully selected after thorough neuropsychiatric study, and it can be stated that this unit made good soldiers out of the majority of the trainees.

It has already been mentioned that the majority of medical officers who were dealing with casualties at the front had a course in first-aid psychiatry. This included prevention as well as early treatment. Also, line officers with combat units were instructed in various ways by Army and division psychiatrists. It can be stated that the division psychiatrist was the keystone of the psychiatric services in combat units. Every division had one. He functioned mainly at the level of the clearing station, where he had one or two tents separate from others for combat-exhaustion patients. An important part of his work was to see that the medical officers in front of him functioned efficiently. Quite early in

combat it was recognized that a division psychiatrist who was having a large percentage of men returned to duty from the clearing station was not doing a good job forward. Numerous examples could be given in which a division psychiatrist had a low rate of return to duty only because medical officers ahead of him sent him only the most difficult cases.

It was originally planned to have psychiatric services in evacuation hospitals, to carry on further study and treatment of patients whom the division psychiatrist had been unable to return to duty. This was the arrangement that existed in the North African theater until November, 1943. At that time the surgeon of the Fifth Army made the suggestion that the Army clearing station be used as a separate neuropsychiatric unit to relieve crowding in evacuation hospitals. The advantages of this arrangement were obvious, and this recommendation was brought back to the European theater of operations. Usually an evacuation hospital is looked on as being primarily a surgical hospital, and when it is crowded the transportable patients, especially the ambulatory ones are sent farther to the rear to make room for the seriously wounded.

Recognizing this possibility, the First Army some months before D Day organized an exhaustion center. This was a makeshift organization using a clearing company as the housekeeping unit, which was augmented by bringing in psychiatrists from evacuation hospitals on detached service. The plan of service and treatment was essentially the same as that described above for the larger neuropsychiatric hospitals in the communications zone. About two weeks after D Day, the exhaustion center of the First Army was functioning on the Continent. By the end of July, it was necessary to establish a second exhaustion center in the First Army, and early in August each of these exhaustion centers had approximately 1000 patients. It is obvious that the evacuation hospitals could not have handled this case load and that the majority of patients would have been evacuated to the hospitals in England.

The Ninth Army adopted this same plan, and the Seventh Army had been using such an arrangement before it came into France. The Third Army differed in that psychiatrists were kept in the evacuation hospitals, but these units were backed up by a special neuropsychiatric section in the convalescent hospital. For the Third Army with its particular type of combat, which was mostly rapid advance, this arrangement worked extremely well. In the end it was decided by most neuropsychiatrists who had had experience at the front that the exhaustion center should be established as an official part of the medical services of each army.

One could go into great detail in describing the various types of neuropsychiatric conditions seen under combat, but only a brief account can be given here. As is well known, the term "combat exhaus-

tion" was the only diagnostic label placed on the emergency medical tag of the neuropsychiatric patient at the front. This diagnosis was not changed unless he was evacuated. There is no doubt that in a few cases a more specific diagnosis could have been made right at first, but in the vast majority of cases this proved to be an excellent term. Naturally, the soldier read his diagnosis and the term "exhaustion" suggested to him a natural occurrence and speedy recovery. Treatment, too, was essentially that of overcoming an exhausted state and included sedation, food, sleep and reassurance. In the majority of conditions arising under combat conditions purely physical causative factors could not be separated from emotional and psychologic factors. The two were mutually contributory, one to the other. The vast majority of men coming back from combat with nervous symptoms were exhausted, and the majority of thoroughly exhausted men showed unsteadiness and even tremors, loss of efficiency, disturbed digestion and complaints of headache, bodily aching and loss of strength. These are the very symptoms seen in the more outspoken neuroses. In ordinary life, fatigue brings aching muscles, the tired business man is irritable, the exhausted child cannot fall asleep, strain often produces headache, and long hours of work lead to lowered efficiency. Usually the psychologic factors are more important, but there is such a thing as exhaustion of psychologic and emotional functions.

Any classification of type of cases is apt to be misleading because within a few hours or a day or two one type often changed into another, and still later and farther back one frequently saw a clinical picture that did not resemble the initial one.

By far the most frequent conditions found were the anxiety conditions. These can be divided into the highly acute and the subacute. In the highly acute conditions there was either panic or freezing. There is no need to describe these in detail, except to say they were extremely disconcerting to others. In the subacute conditions, rhythmic tremor was usually outstanding and a startle reaction was prominent. These soldiers looked exhausted and gave a history of having had little sleep and a loss of appetite. For many of them, battle dreams were quite disturbing.

At the front, clear-cut hysterical conditions were not so frequent as might have been expected, judging from the history from the last war. The obvious hysterical paralyses were in the minority, and the most frequent hysterical symptom was amnesia. After this came loss of voice or stuttering, and there were occasional patients with hysterical blindness or deafness. Not infrequently a patient who had first appeared with an anxiety condition later showed some hysterical symptoms as his outspoken anxiety symptoms diminished.

After a unit had been in combat for a long time, the proportion of patients with what was called "re-

active depression" increased. These syndromes came mostly in conscientious noncommissioned officers who had been at the front for a long time. They appeared definitely exhausted and depressed, with self-accusatory trends. Mention should also be made of the pseudopsychotic cases. These patients seemed hallucinated and disoriented and sometimes presented a typical catatonic picture. The psychotic symptoms rapidly subsided but often left anxiety or hysterical syndromes.

In discussing the topic of treatment it is appropriate to consider prevention because there is no distinct dividing line between prevention and treatment. As stated above, line officers as well as all division medical officers had some indoctrination in prevention and early recognition of combat exhaustion, but perhaps not enough. In this training, emphasis was placed on the quality of leadership as a primary factor in prevention. It was considered important that soldiers be fitted into their proper assignment so the job was neither too big nor too little for their abilities and training. Selection, classification and assignment was considered a continuing process in all units. Adequate training, indoctrination and discipline were important because they added to the soldier's confidence in taking care of himself. Another item in prevention was the way in which reinforcement troops were introduced into the unit during fighting. The problem of providing adequate rest periods for smaller or larger units was a topic of constant discussion. Rest periods were instituted wherever the tactical situation allowed. It was considered better to do this than to wait for the soldier to become a medical casualty. Such rest periods gave him something better to look forward to than death, maiming or a psychiatric breakdown. The medical officer with combat troops was schooled to be on the lookout for the man who was getting jumpy, going off by himself, becoming sleepless, losing his appetite or showing other symptoms of undue strain. He was urged to see that his men were as comfortable, well fed and clean and dry as possible under any given set of circumstances. He was also told that a good medical officer had an interest in the soldiers' everyday life, in their sports and in their equipment and that he had to share their dangers and hardships.

Concerning treatment more specifically, the front-line medical officers did recognize early symptoms, and the usual procedure was to send the soldier back to the kitchen area or some similar place where he could have a good sleep, perhaps with a little sedation, one or two hot meals and a chance to wash, shave and dry his clothing. Of course the personal contact, the explanation and reassurance given and the temporary relief from constant vigilance were important factors in this first-aid work. Just how many men were so treated and returned to duty the following day is not known because no records could be kept, but there were cer-

tainly many of them. Several division surgeons told me that at least 50 per cent of the combat-exhaustion patients were returned to duty in this way.

If the symptoms were too pronounced for this simple treatment, the soldier was evacuated, under sedation, to the clearing station. Sedation during this process seemed to render the job easier and made the patient more comfortable. Certainly patients arriving at the clearing station under sedation were in much better condition than those sent back without it. Also, it appeared that fixation of symptoms was in some measure prevented.

At the clearing station the patient was kept under the care of the division psychiatrist for two to four days. For the majority of patients so held, sleep during the first twenty-four to thirty-six hours was assured, with due attention to nutrition. Sodium amytal was used, so that the patients slept through the night and had a nap in the forenoon and afternoon. At least another day was given to occupation, recreation and group or individual talks. In some divisions more extensive rehabilitation programs were tried. At this level, hysterical symptoms usually responded readily to suggestive therapy, with or without the aid of drugs.

At the exhaustion center the patients could be held longer—for seven to ten days—and the treatment, especially the rehabilitation program, could be carried out much more thoroughly. Moderate sedation was used for the first few days, and occasionally modified insulin therapy was employed. Group psychotherapy and individual psychotherapy where indicated were considered of the greatest importance.

Reference to treatment in the neuropsychiatric units in the Zone of Communications has already been made. Moderate sedation therapy was extensively employed, but this was frequently com-

bined with modified insulin therapy. Group and individual psychotherapy often started with the above treatment and was always carried on so far as necessary or so far as time permitted. In individual psychotherapy, Sodium Pentothal abreaction was used more frequently than was hypnosis. Some neuropsychiatrists thought that group psychotherapy was the most valuable of all forms of treatment. Others thought that in the majority of cases the individual working out of problems, with or without drugs or hypnosis, was necessary. The modified insulin therapy, which was undoubtedly instrumental in the gain in weight and physical well-being, could not have been left out in the majority of cases. It can be added that without the rehabilitation program the return-to-duty rate would not have been nearly so high.

Regardless of what type of treatment was the most efficacious, it is known that within Army psychiatric services, 60 per cent of the patients were returned to active duty, and that the majority of them resumed combat duty. This does not count the patients who were returned to duty up forward at the aid stations. At this rate, 40 of every 100 patients came back to the Zone of Communications. There the neuropsychiatric hospitals were able to return approximately 80 per cent to duty, but mostly noncombat duty. This leaves only 8 or 10 of the original 100 patients for evacuation to the Zone of the Interior. Among these were a few psychotic and epileptic patients and others who could not possibly be reclaimed for service.

There are many more interesting topics that might be discussed, such as morale, individual case studies, motivation of the soldier, selection and placement and personality factors in those suffering breakdowns. All these topics deserve separate papers. It is hoped that the above description has given some idea of the over-all developments in neuropsychiatry in the European Theater of Operations.

INFECTIOUS DIABETIC GANGRENE OF THE SKIN OF THE NECK

Report of a Case

JOSEPH MILLETT, M D,* AND RICHARD T DARBY, M D*

HEMPSTEAD AND VALLEY STREAM, NEW YORK

WHEN diabetes mellitus and gangrene are associated, one usually thinks of this combination in relation to the extremities, along with arteriosclerotic peripheral vascular disease. Gangrene of other parts of the body is considered to be a rare complication of diabetes mellitus. Nevertheless a growing, if scattered, literature on this complication is accumulating. There has been reported diabetic gangrene of the nasal septum and turbinates,¹⁻⁵ the orbit and nares,^{5, 6} the nares alone,^{7, 8} the right half of the tongue,⁶ the lip,⁹ the skin of the entire body,¹⁰ the face,^{5, 6, 11-13} the lung,¹⁴ the vulva¹⁵ and the glans penis and urethra.¹⁶

It is our purpose to report a case of diabetic staphylococcal gangrene of the skin of the entire neck. This complication of diabetes mellitus presented some interesting features regarding the differential diagnosis, the prognosis and, in particular, the treatment.

CASE REPORT

J H, a 51-year-old salesman, was admitted to the South Nassau Communities Hospital in Rockville Centre, New York, on May 5, 1944. His illness began 10 days before admission, when he noted some pain in the back of the neck, which progressed to redness and swelling. The pain and swelling, which had begun at the nape of the neck, spread over the entire neck, and the patient began to run a fever. He treated himself with hot compresses, and 2 days before admission consulted one of us (R T D), who suspected a beginning carbuncular lesion secondary to diabetes mellitus and advised hospitalization. No history of trauma could be obtained.

The past history revealed diabetes of many years' standing. Twelve years previously the patient had an abscess on his forehead, which was extremely painful and slow to heal. The family history was noncontributory.

Physical examination revealed an obese, stocky man. It was essentially negative except for the obesity, a heart that was enlarged to the left, a blood pressure of 180/94 and the neck lesion. The patient appeared acutely ill.

The lesion on the neck extended from slightly above the hair line to the shoulders and laterally around to the line of the ear lobes on both sides. It was raised but flat and was red and brawny in appearance. There was no sharp line of demarcation. There was no evidence of the typical multiple-headed boil characteristic of carbuncle. The red-cell count was 4,500,000, and the hemoglobin 12.6 gm. The white-cell count was 25,000, with 80 per cent neutrophils, 13 per cent small lymphocytes, 5 per cent monocytes, 1 per cent basophils and 1 per cent eosinophils. The urine contained 10 per cent sugar and gave a +++ test for acetone, the test for diacetic acid was negative. The blood-sugar level was 200 mg per 100 cc.

The patient was treated vigorously for diabetic acidosis with insulin and intravenous fluids. Seven days after admission the urine was clear of sugar and acetone. The patient ran a septic temperature ranging from 99 to 104°F.

Shortly after admission the red, brawny area suddenly became cyanotic and in 24 hours it became gangrenous. The gangrene was sharply demarcated. Small, scattered crops of blebs filled with fluid appeared, these soon broke and began to discharge pus. A culture of this material revealed *Staphylococcus albus* and *Staph aureus*. The patient was seen by one of us (J M), at which time a diagnosis of diabetic staphylococcal gangrene of the skin was made. Conservative treatment was advised, inasmuch as the diagnosis of carbuncle of the neck had been entertained and surgical treatment was anticipated. The lesion did not present any of the characteristics of the multiple-headed boil discharging pus from many openings that is usually associated with carbuncle.

Further laboratory studies of the blood and urine are shown in Table 1.

At first, borie acid wet dressings were applied locally to the gangrenous areas with the intention of localizing the infection, without effect. For a while there was mild drainage from the blebs.

On the 5th day after admission, treatment with penicillin was begun. A dose of 1,300,000 units was given intramuscularly in the buttock and locally around the lesion dur-

TABLE 1 Laboratory Data

	URINE			BLOOD SUGAR
	SUGAR	ACETONE	DIABETIC ACID	
5-8-44	4%	++++	++	mg /100 cc
5-11	2%	++	0	
5-12	Trace	0	0	
5-13	0	0	0	
5-15	0	0	0	220
5-18	0	0	0	
5-22	0	0	0	190
5-26	0	0	0	102

ing a period of 3 days. In the last few days of hospitalization only dry dressings were used. The temperature, which had been ranging up to 104°F, dropped to 101.2° for 2 days and after the 7th day averaged 100.4° for 3 days and 100° for 10 days. It was normal on the day of discharge, March 25. The patient left the hospital with the entire back of the neck covered with a typical dry, purple gangrene (Fig 1), which was as extensive as the day the neck became gangrenous.

The patient was last seen on July 11, 1944, at which time the faintest blush could be seen where the former area of gangrene had been (Fig 2). There were a few scattered punctate areas, where former blebs were still in the process of granulation. Aside from this the skin appeared normal. The diabetes was under control, and the patient was quite well.

DISCUSSION

The clinical diagnosis of diabetic staphylococcal gangrene of the skin offers little difficulty once the gangrene appears. In the early stages of the infection it may be mistaken for erysipelas. This diagnosis has been made on several occasions.^{6-8, 11} Another lesion that resembles erysipelas in its early stages and later becomes gangrenous is hemolytic streptococcus gangrene of the skin, described by Meleney.¹⁷ The differentiation is established by bacteriologic examination.

*Staff physician, South Nassau Communities Hospital, Rockville Centre, New York.

The mechanism producing this type of gangrene is distinct. Buerger,¹⁸ in describing the diagnosis and pathologic process of the so-called "diabetic gangrenes," draws attention to four distinct varieties of the disease—the arteriosclerotic, the thrombotic, the embolic and the thromboangitis obliterans form. The essential features of these types may be described briefly as follows. The arteriosclerotic

thrombus formation. This type likewise is most frequent in the peripheral vessels. Embolic gangrene is a sequel to the lodging of an embolic mass, which is frequently carried from some distant focus and when infected leads to suppuration, abscess formation and gangrene. This type of gangrene may occur in vessels that are otherwise normal. Thromboangitis obliterans is characterized by in-

FIGURE 1 Photograph Taken Several Days before Discharge from the Hospital

type occurs in persons of advanced years and involves the larger arteries, especially those of the periphery, in vessels that are the site of advanced arteriosclerosis. It is characterized by proliferation of the endothelial lining, with an increase of the subendothelial connective tissues, as well as by fatty degeneration, with the deposition of fat, lipoids and cholesterol. The necrosis is associated with atrophy and calcification of the tunica muscularis and the tunica adventitia, leading to occlusion.

Thrombotic gangrene occurs in vessels that are the site of arteriosclerosis of a mild degree and is characterized by sudden occlusion as a result of

involvement of the superficial veins and arteries by an acute inflammatory process, resulting in thrombus formation and subsequent occlusion.

There are several predisposing factors to be considered in the production of diabetic gangrene of the skin. First of all, there is the diabetic patient, who is always susceptible to infection. Trauma to the skin, however slight, may be a precipitating factor. The ever-present staphylococcus needs little more encouragement for invasion under such circumstances. The resulting brawny inflammation and edema may produce an arteritis of the terminal ves-

sels in the skin, with thrombosis and subsequent gangrene of the parts supplied.

The edema beneath the surface of the lesion may lend a misleading appearance regarding the depth of the gangrene. The gangrene in the present case must have been superficial indeed to have cleared

a large crater with undermined edges. Occasionally in this type of lesion one sees small areas of gangrene of the skin about the edge of the crater.

Unlike diabetic gangrene of the extremities, age apparently plays no role in this type of gangrene. The youngest patient on record was four years of

FIGURE 2 Photograph Taken a Month and a Half after Discharge from the Hospital

up without the skin's sloughing out *en masse*, as might have been expected from its appearance. It was only in the scattered areas where the blebs containing clear fluid appeared, later to discharge pus, that the gangrene was deep enough to produce actual necrosis of the entire depth of the skin, with subsequent replacement by scar tissue. These areas were small as compared to the actual amount of skin surface involved. From a pathological and clinical point of view, this tends further to distinguish this lesion from carbuncle, in which there is usually a large central necrotic area discharging pus from many small openings in the skin. This deep necrotic lesion if left alone eventually sloughs out and leaves

age, followed by 1 eight years and 2 ten years of age. The oldest patient was sixty-five years of age.

The prognosis of diabetic gangrene of the skin is uniformly favorable. The only exceptions are the lesions that involve the cheek over the malar areas. The lesion in this location easily spreads into the blood vessels leading inside the skull, resulting in cavernous-sinus thrombosis, brain abscess and meningitis or drainage into the general circulation with bacteremia and metastatic abscesses. All these patients have died.^{5, 6, 11, 12} All patients with lesions involving other areas about the head, the nasal septum and turbinates, the hard palate, the eyelids, the skin of the nose and ears, the lip and

the tongue have recovered, with one exception (Bowers's⁵ Case 1), and this death occurred in the pre-insulin era

The complications following diabetic gangrene of the body surfaces depend on the extension of the lesion to adjacent structures. Thus, in Morris's¹ case, involvement of the turbinates and septum was complicated by involvement of the adjacent sinus and the third, fourth and ophthalmic branch of the fifth and sixth nerves. In Briers's case, involvement of the skin of the ear and the area anterior to it was complicated by involvement of the fifth and seventh nerves. In Ardeshir's⁸ case, gangrene of the skin of the nose was accompanied by destruction of the underlying cartilage of the nasal alae, whereas Wood's⁷ case resulted in spontaneous amputation of the entire nose and the loss of the nasal septum and the nasal processes of the superior maxilla and nasal bones. Goldberg's³ case of gangrene of the nasal cartilage and right middle and inferior turbinates resulted in osteomyelitis of the right orbit, and Speidel's⁴ case of gangrene of the nasal septum ended with atrophy of the right optic nerve. Millett¹¹ has shown in his 2 cases of gangrene of the cheek that where the extension of the infection had involved the general circulation, positive blood cultures for staphylococci were obtained, and that in the case that came to autopsy metastatic abscesses were found in the lungs. The organisms cultured from the cheek lesion and from the blood stream were identical.

The proper treatment of diabetic gangrene of the skin is both general and local. The diabetes and any acidosis present must be controlled by insulin, fluids and dextrose. Local treatment should in the main be conservative. Watchful waiting is probably the procedure of choice. Wet dressings and careful removal of slough as it occurs can be done as needed. Penicillin may well prove to be a life-saving procedure when septicemia is present. It should be used at all times in these cases, since it

may well prevent such a complication. Drastic surgery should not be done, since it may open up new channels for systemic invasion by organisms.

SUMMARY

A case of extensive infectious diabetic gangrene of the skin involving the entire neck is reported. The patient recovered.

Infectious diabetic gangrene of the skin may be considered as a separate clinical entity having a distinct clinical course and a definite pathology.

In differential diagnosis it must be considered with erysipelas in its early stages and carbuncle in its later stages.

Conservative treatment should be given. Penicillin may be life-saving in preventing septicemia or in overcoming it when it occurs.

MEDICAL PROGRESS

ENDOSCOPY*

EDWARD B. BENEDICT, M.D.†

BOSTON

ALTHOUGH endoscopy may seem to be a narrow specialty, many of the most interesting diagnostic problems in the hospital eventually come to some form of endoscopic examination. As will be seen in the following review, these include many pulmonary problems that may need bronchoscopic study, gastrointestinal problems, which often require a direct inspection by esophagoscopy or gastroscopy, and various abdominal conditions, such as hepatomegaly, unexplained ascites and abdominal or pelvic masses, which may be satisfactorily studied by peritoneoscopy.

BRONCHOSCOPY

Congenital Anomalies

Ferguson and Neuhauser¹ report 5 cases of agenesis of the lung diagnosed during life by bronchoscopy, followed by iodized oil roentgenograms of the tracheobronchial tree. These cases illustrate the fact that this deformity is not incompatible with a normal existence, since 4 of the patients are living normal lives and are not handicapped by their defect.

Gross and Lewis² report the case of a four-year-old child who had a large opening in the anterior mediastinum, a free interpleural communication and an anomaly of the right upper-lobe bronchus. The bronchus was not more than 4 or 5 mm in diameter. When freed adequately from overlying tissue so that it could be palpated, it was found to be soft and apparently devoid of cartilage in the exposed section. This deficiency allowed the airway to collapse in such a manner that air entered the upper lobe and became entrapped therein. Marked emphysema of the right upper lobe allowed it to protrude through the mediastinal opening and invade the left pleural cavity. The patient had intermittent attacks of severe respiratory distress, dyspnea and cyanosis, which were completely relieved by simultaneous closure of the anterior mediastinal defect and removal of the anomalous right upper lobe. This is apparently the first recorded case of surgical repair of an anterior mediastinal defect. In retrospect, one wonders whether this patient might not have been cured by right upper lobectomy alone. Although this possibility is freely admitted, it seemed to the authors at the time of

operation that limitation of the surgical correction to lobectomy might be followed by subsequent distention of the left lung so that it would project through the free space in front of the heart. In order to prevent any such shift, it was believed that obliteration of the anterior mediastinal space was necessary to ensure against any recurrence of respiratory difficulties.

Gross³ has reported a case of tracheal obstruction from a vascular ring relieved surgically. The case was that of an infant who was proved to have tracheal compression from a vascular ring within the mediastinum. The obstruction was particularly troublesome because of repeated attacks of superimposed tracheitis, for which the patient was hospitalized on four different occasions. Roentgenologic studies showed evidence of a vascular ring, and at operation the vessels were suitably divided to allow sufficient room for the trachea. The patient tolerated this surgical procedure extremely well and had marked alleviation of symptoms. The detection of a vascular ring is apparently not difficult. Since in the vast majority of these patients some portion of the ring passes behind the esophagus, fluoroscopic observation after a swallow of barium should show indentation of the posterior wall of the esophagus. If such esophageal deformity is found, the trachea can be studied by the introduction of lipiodol and by appropriate film studies in the anteroposterior and lateral views to detect any constriction of the trachea that may exist. Vascular rings do not always give rise to important clinical symptoms, but when the compression of the trachea is great enough to give rise to respiratory distress, surgical division of some portion of the ring should offer an excellent chance for relief of symptoms.

Bronchiectasis

Stookey, Lockwood, Mantz and Buckingham⁴ studied penicillin therapy in bronchiectasis. The bacteriologic findings demonstrated that little aid resulted from the use of sulfonamide drugs. Staphylococci were the most consistent and persistent of the pathogens. The most frequent combination was one form of the staphylococcus with *Streptococcus viridans*. Twenty-one patients received an average of 1,000,000 units of penicillin by intramuscular and intravenous injection in eight to ten days. The volume of sputum was not influenced,

*From the Massachusetts General Hospital.

†Instructor in surgery, Harvard Medical School; endoscopist, Massachusetts General Hospital.

but from a clinical standpoint cases showed evidence of improvement. Chronic bronchitis associated with periods of activity and remission gave the best hope of therapeutic response. The true bronchiectatic patient showed little or no response to penicillin. I believe, however, that in inoperable cases of bronchiectasis, penicillin inhalations combined with postural drainage and bronchoscopic aspiration offer the best hope of palliative relief.

Thomas, Van Ordstrand and Tomlinson⁵ studied 75 cases of bronchiectasis treated by sulfonamides or allergic management or both. In 57 cases, lipiodol bronchography and bronchoscopy established the diagnosis. Twenty-three of these patients showed definite improvement, with a reduction of cough and expectoration while under treatment. In 31 cases, combined allergy and sulfonamide therapy was used. Twenty-six patients showed 25 to 100 per cent improvement in cough and expectoration.

In a symposium on bronchiectasis by members of the Mayo Clinic, Hinshaw⁶ calls attention to the fact that bronchiectasis should not be discussed without mention of the many pitfalls in diagnosis. Obstructive lesions, such as bronchiogenic carcinoma, bronchial adenoma, foreign bodies and inflammatory stricture of a bronchus, should also be emphasized. Furthermore, tuberculosis may occur in any portion of the lung, and when it is present in a lower lobe it may resemble bronchiectasis.

Olsen⁷ believes that foreign bodies, bronchial tumors, broncholiths, bronchial strictures and bronchial compression must be ruled out by bronchoscopic examination. It is his opinion that bronchoscopy should be performed in the majority of cases of suspected bronchiectasis. Furthermore, the bronchoscopist can frequently play an important part in the prevention of bronchiectasis. The timely removal of an aspirated foreign body almost invariably prevents the development of pulmonary suppuration. Bronchial obstruction due to neoplasms or broncholiths may be relieved by bronchoscopic means, and in many cases permanent damage to the bronchi may be avoided. Pulmonary atelectasis not infrequently occurs after surgical procedures when thick, tenacious secretions become impacted in the bronchi. Bronchoscopic aspiration of these secretions should be carried out early if bronchial disease and pulmonary complications are to be prevented. When a pneumonic process fails to resolve, bronchial complications should be suspected.

Clerf⁸ thinks that bronchoscopy is of value in bronchiectasis only as a diagnostic aid and as a palliative measure preparatory to carrying out surgical treatment. In cases of obstructive bronchiectasis a diagnostic bronchoscopy is absolutely indicated before surgical intervention, since there may be present a foreign body, stricture of the bronchus or benign neoplasm, any of which may seriously complicate the surgical result. All cases of unilateral bronchiectasis should be considered as

surgical problems, since no cure can be obtained by bronchoscopy alone. Its use would, therefore, deprive of a cure a patient suitable for surgical treatment.

Foreign Bodies

Hammond⁹ reports an emergency cervical mediastinotomy in a case of massive mediastinal and subcutaneous emphysema secondary to removal of a foreign body from the bronchus. The foreign body was a piece of apple, found in the orifice of the left main bronchus. A piece of it was removed with forceps, following which the remaining portion was suddenly and forcibly expelled through the bronchoscope. Twenty minutes later the author was urgently called to the pediatric floor to see the patient. Swelling of the tissues of the neck and the upper chest was noted, following which respirations became labored and the abdomen began to swell. The picture was extraordinary. The whole body was emphysematous, particularly the abdomen, which had the appearance of a balloon that was rapidly becoming overinflated with each respiration. The eyelids were bulging, and the scrotum was as large as two adult fists. Creptitation was noted over the entire body, extending to the fingers and toes. Immediate cervical mediastinotomy was decided upon. A midline incision was made from the thyroid notch to the sternum. There was a sudden gush of air from the subcutaneous tissues. Abdominal tension was relieved by multiple needle punctures under the skin. Within a few minutes, respirations appeared normal, and the wound was lightly packed with vaseline iodoform gauze and the patient returned to bed. Hammond concludes as follows:

A check-valve obstruction of the bronchus by a vegetal foreign body is reported in a child. The increased pulmonary pressure secondary to a foreign body in the bronchus was aggravated by the straining during bronchoscopy. A rupture of the alveoli followed, with the escape of air along the blood vessels to the mediastinum, following which there was generalized extension of air over the whole body by way of the blood vessel sheaths. The rapid and continuous passage of air into the body tissues led to marked ballooning and extreme cyanosis. Fatal termination was prevented by an emergency cervical mediastinotomy.

Adenoma

Clerf⁸ calls attention to the fact that in the earlier cases of adenoma it was not known that many of these tumors presented an extrabronchial as well as an endobronchial portion. Bronchoscopic methods of therapy were therefore instituted, and remarkably good results were secured in a number of cases. If one can determine by bronchoscopy and tomographic studies that the tumor is endobronchial, it may be successfully treated by diathermy. If there is an extrabronchial portion, however, surgical extirpation will ultimately become necessary. Clerf has found it necessary to have a number of his earlier cases submit to surgical treatment. Although there are observers who believe that this is

a malignant tumor, few cases of implants either in the lung or in other tissues have been recorded

Jackson, Konzelmann and Norris¹⁰ have studied the clinical features of 20 cases of so-called "adenoma of the bronchus." They believe that infiltration of the bronchial wall is possible, but that it is sufficiently infrequent and limited when it does occur so that endobronchial removal is justified when it can be done, it being admitted that complete removal by this means is often not possible and that obviously incompletely removed tumors will recur. That these tumors may undergo malignant change must be admitted. The experience of the Jackson Clinic indicates that malignant change is infrequent. These authors do not believe that adenomas have any inherent tendency to metastasize or become malignant in any other way. None of their patients have shown such a course, although a number have been under observation for ten years or longer. The possibility of extrabronchial growth of adenomas, producing a so-called "collar-button" lesion with the larger part outside the bronchus, is recognized but is thought by many to have been overemphasized. Bronchoscopic treatment by forceps removal, electrocoagulation and aspiration is indicated as the first step in all cases, it is curative in some and palliative in others. In cases in which there is atelectasis or bronchiectasis, a preoperative course of bronchoscopic treatment is indicated, even if lung resection has been definitely decided on or is to be considered at a later date. Lobectomy or pneumonectomy is indicated when bronchoscopic cure of the bronchial lesion seems impossible, or when prolonged bronchial obstruction has resulted in serious permanent damage to the distal portion of the lung.

Graham and Womack¹¹ have also discussed so-called "bronchial adenoma," stating that the chief clinical problem that these tumors present concerns the question of whether they are to be regarded as either actually or potentially invasive in nature or should be considered purely benign in type. It is difficult to understand how there could be any controversy on the point at this time. If one accepts as criteria of malignancy invasion of adjacent tissues, involvement of regional lymph nodes and metastasis to distant organs, then in the light of a considerable amount of published experience one cannot deny that there have been authentic cases in which these tumors have become malignant, for many cases have been recorded in which these three criteria mentioned have been present. In view of the well established malignant potentialities of bronchial adenoma, the principles of treatment become clear. It seems to Graham and Womack that radical surgical removal is the procedure of choice. Because of the frequency with which one finds a large portion of the tumor outside the bronchus, it appears that only rarely can it be completely removed through the bronchoscope. In many cases

such an attempt is particularly hazardous because of the danger of perforation of the bronchus. If the tumor is not completely removed, there will always be the danger of a later invasion by the part left behind, as in the case cited by Burrell¹² and that of Graham and Womack. An additional objection to the local removal of the tumor is the uncertainty in many cases of whether it is actually malignant at the time of operation, and if so, the extent of its spread. The piece of tissue that has been removed by bronchoscopy for biopsy may not show clear evidence of malignancy, even when the tumor has already invaded neighboring tissues or regional lymph nodes. Still another reason why bronchoscopic removal is likely to be unsatisfactory is that there is often an associated bronchiectasis, supposedly due to the bronchial obstruction produced by the tumor. Undoubtedly lobectomy sometimes proves to be an adequate operation, but it is Graham and Womack's opinion that often it is not adequate because of the location of the tumor. They therefore prefer the operation of total pneumonectomy for these cases. The removal of possibly involved regional lymph nodes can be much more satisfactorily accomplished in this way. In good-risk patients there is scarcely if any greater danger from the operation of total pneumonectomy than from lobectomy. In conclusion, these authors are in disagreement with Jackson,¹⁰ believing that the frequent inability to determine from a biopsy specimen whether the tumor has already become malignant makes an attempt at local removal through the bronchoscope both unwise and dangerous. They claim that total pneumonectomy is the procedure of choice.

In a discussion of the above paper, Alexander states that he and Dr. Haight and their pathologist, Dr. Carl Weller, all agree that so-called "adenoma" is a Grade 1 carcinoma.¹³ They believe that the risks of hemorrhage, of recurrence and particularly of transition to a more active type of malignancy than Grade 1 carcinoma, or from the fetal stage to a true carcinoma stage, together with the great ultimate risk to life of suppuration of the lung and pleura, far outweigh the risks of expertly performed lobectomy or pneumonectomy.

In reply to Alexander's remarks, Jackson¹³ stated that in his cases he had not had any cases of "frightful" hemorrhage from an adenoma. He believes that the way to minimize the risk from hemorrhage is not to try to do too much at one time. Biopsy is enough for the first time, then electrocoagulation, subsequently alternating forceps removal with electrocoagulation at appropriate intervals, removing the obstructive lesion in a series of bronchoscopies rather than trying to effect a cure in one treatment.

Holinger¹³ states that in his experience the question of hemorrhage is one that influences the choice of therapy. If a tumor has a tendency to bleed profusely when efforts are made bronchoscopically to

free the affected bronchus, bronchoscopic removal is discontinued and surgical resection is advised. He believes that cases with a marked tendency toward bleeding are definitely not bronchoscopic problems.

In a continuation of this discussion, Graham¹³ states that bronchial adenomas are potentially malignant. In his clinic he knows of more than 10 cases in which there have been regional or distant metastases from tumors that began as adenomas with a long history.

Tyson and Milliken¹⁴ think that recently there has been a swing toward the viewpoint that adenoma is usually benign but may become malignant. Because of irreparable lung damage beyond the tumor and the possibility of extrabronchial extension of the tumor, they concluded that in the case reported a pneumonectomy was necessary. Examination of the surgical specimen showed that the adenoma had protruded through the posterior surface of the bronchus in a collar-button manner, the extrinsic portion being about a fourth as large as the portion within the lumen. The middle and lower lobes were completely obstructed and their bronchi were filled with mucopurulent material. The patient's only symptom four years after the operation is some shortness of breath and wheezing if she walks rapidly up a steep hill. She is able to carry on her housework and her duties as a telephone operator without respiratory embarrassment.

Chamberlain and Gordon¹⁵ also favor pulmonary resection for bronchial adenoma. Although these tumors were first treated by endobronchial removal, these authors believe that pulmonary resection is preferable for the following reasons. It offers a definitive cure, the hazards associated with the damaged lung distal to the tumor are avoided, and some of these tumors are potentially malignant and occasionally metastasize. Endobronchial removal is indicated in four groups of cases — those that are not reasonable surgical risks, those that involve the trachea, those with abscess distal to the tumor, which are best prepared for subsequent resection through improvement in the bronchial drainage, and the rare cases in which the tumor is entirely within the bronchus, easily accessible and attached by a long, slender pedicle. These authors report 10 cases all having the same fundamental features characteristic of bronchial adenoma, the extrabronchial portion in each case being larger than the endobronchial element. Pulmonary resection completely removes the tumor and the irreparably damaged lung distal to the obstruction. At operation mediastinal nodes should also be removed, since they are occasionally involved. Endobronchial therapy, although favorably reported on, lacks the advantage mentioned and has some disadvantages. It requires repeated manipulations, since local recurrences are frequent, and the risk of severe hemorrhage is always a consideration. Cicatrization may

occur following repeated bronchoscopic treatments, with or without the use of radon. Such scarring and stenosis interfere with the cleansing mechanism of the bronchus — ciliary action and bronchial peristalsis — and predispose to pulmonary suppuration. The principal therapeutic objective is maintaining a patent airway if cicatricial stenosis is substituted for an obstructing tumor. Even in the absence of scarring and local recurrence stenosis may occur.

Clerf and Bucher¹⁶ have noted in cases treated by bronchoscopy that after years of freedom from symptoms and no recurrence of the growth endobronchially, there is progressive narrowing of the bronchial lumen by either an intramural or an extrabronchial growth. It is of interest that the cause of death in these cases is usually due to pleural and pulmonary suppuration, secondary to the bronchial obstruction, and occasionally to hemoptyses following bronchoscopic manipulation, yet there is no record of a death due to metastases.

Harrill¹⁷ reports a case of adenoma of the trachea, the most prominent clinical feature of which was tracheal obstruction. Adenoma arising from the upper part of the trachea is rare. A tracheotomy was done, and the mass was later removed by forceps through a tracheoscope.

Cylindroma

McDonald, Moersch and Tinney¹⁸ have reported 6 cases of cylindromas of the bronchus. Histologically, cylindroma presents a different appearance from that of adenoma of the bronchus and appears to be more allied to mixed tumors. The clinical course is remarkably similar to that of adenoma. The bronchoscopic appearance of the tumor is also similar to that of adenoma. Bronchiectasis and lung abscess are frequent sequelae to the long-standing obstruction produced by the tumor.

Carcinoma

Overholt and Wilson¹⁹ have recently discussed silent and masquerading intrathoracic lesions. They believe that the figures regarding the bronchoscopic diagnosis of bronchiogenic carcinoma are misleading. They state that the medical literature abounds with statistics indicating that 70 to 75 per cent of all bronchiogenic carcinomas originate in the major bronchi and are thus visible through the bronchoscope and accessible for biopsy. They believe that these figures are false when applied to early carcinoma of the bronchus. If bronchoscopy is performed early, it is negative in 40 per cent of the cases because the site of origin is beyond bronchoscopic view. Bronchoscopy is, therefore, an unreliable guide when the results are negative, since it does not in any way exclude the presence of the tumor immediately beyond the vision of the bronchoscopist. They believe that in the diagnosis of early cancer bronchoscopy is about 50 per cent inefficient, furthermore, a negative bronchogram in no way

a malignant tumor, few cases of implants either in the lung or in other tissues have been recorded.

Jackson, Kosselmann and Nemis¹¹ have studied the clinical features of 55 cases of so-called "adenoma of the bronchus." They believe that infiltration of the bronchial wall is possible but that it is sufficiently infrequent and limited when it does occur so that endobronchial removal is justified when it can be done, it being admitted that complete removal by this means is often not possible and that obviously incompletely removed tumors will recur. That these tumors may undergo malignant change must be admitted. The experience of the Jackson Clinic indicates that malignant change is infrequent. These authors do not believe that adenomas have any inherent tendency to metastasize or become malignant in any other way. None of their patients have shown such a course, although a number have been under observation for ten years or longer. The possibility of endobronchial growth of adenomas, producing a so-called "collar-bronchus" lesion with the larger part outside the bronchus, is recognized but is thought by many to have been overemphasized. Bronchoscopic treatment by forceps removal, electrocoagulation and aspiration is indicated as the first step in all cases; it is curative in some and palliative in others. In cases in which there is atelectasis or bronchiectasis, a preoperative course of bronchoscopic treatment is indicated, even if lung resection has been definitely decided on or is to be considered at a later date. Lobectomy or pneumonectomy is indicated when bronchoscopic cure of the bronchial lesion seems impossible or when prolonged bronchial obstruction has resulted in serious permanent damage to the distal portion of the lung.

Graham and Wronski¹² have also discussed so-called "bronchial adenoma," stating that the chief clinical problem that these tumors present concerns the question of whether they are to be regarded as either actually or potentially invasive in nature or should be considered purely benign in type. It is difficult to understand how there could be any controversy on the point at this time. If one accepts as criteria of malignancy invasion of adjacent tissues, involvement of regional lymph nodes and metastasis to distant organs, then in the light of a considerable amount of published experience one cannot deny that there have been authentic cases in which these tumors have become malignant, for many cases have been recorded in which these three criteria mentioned have been present. In view of the well established malignant potentialities of bronchial adenoma, the principles of treatment become clear. It seems to Graham and Wronski that radical surgical removal is the procedure of choice. Because of the frequency with which one finds a large portion of the tumor outside the bronchus, it appears that only rarely can it be completely removed through the bronchoscope. In many cases

such an attempt is particularly hazardous because of the danger of perforation of the bronchus. If the tumor is not completely removed, there will always be the danger of a later invasion by the part left behind, as in the case cited by Bunnell¹³ and that of Graham and Wronski. An additional objection to the local removal of the tumor is the uncertainty in many cases of whether it is actually malignant at the time of operation and if so, the extent of its spread. The piece of tissue that has been removed by bronchoscopy for biopsy may not show clear evidence of malignancy, even when the tumor has already invaded neighboring tissues or regional lymph nodes. Still another reason why bronchoscopic removal is likely to be unsatisfactory is that there is often an associated bronchiectasis, supposedly due to the bronchial obstruction produced by the tumor. Undoubtedly lobectomy sometimes proves to be an adequate operation, but it is Graham and Wronski's opinion that often it is not adequate because of the location of the tumor. They therefore prefer the operation of total pneumonectomy for these cases. The removal of possibly involved regional lymph nodes can be much more satisfactorily accomplished in this way. In good-sized patients there is scarcely if any greater danger from the operation of total pneumonectomy than from lobectomy. In conclusion, these authors are in disagreement with Jackson¹¹ believing that the frequent inability to determine from a biopsy specimen whether the tumor has already become malignant makes an attempt at local removal through the bronchoscope both useless and dangerous. They claim that total pneumonectomy is the procedure of choice.

In a discussion of the above paper, Alexander states that he and Dr. Haight and their pathologist, Dr. Carl Walker, all agree that so-called "adenoma" is a Grade I carcinoma.¹⁴ They believe that the risks of hemorrhage, of recurrence and possibility of transition to a more active type of malignancy than Grade I carcinoma, or from the final stage to a more carcinoma stage, together with the great ultimate risk to life of suppuration of the lung and pleura, far outweigh the risks of expertly performed lobectomy or pneumonectomy.

In reply to Alexander's remarks, Jackson¹⁵ stated that in his cases he had not had any cases of "highly fatal" hemorrhage from an adenoma. He believes that the way to minimize the risk from hemorrhage is not to try to do too much at one time. Biopsy is enough for the first time, then electrocoagulation, subsequently electrosecting forceps removal with electrocoagulation at appropriate intervals, removing the obstructive lesion in a series of bronchoscopic rather than trying to effect a cure in one treatment.

Hilfinger¹⁶ states that in his experience the question of hemorrhage is one that influences the choice of therapy. If a tumor has a tendency to bleed profusely when efforts are made bronchoscopically,

genic carcinoma must be promptly differentiated from tuberculosis, since time and rest never cure a malignant growth. Waiting six weeks or longer for results of animal inoculation or tests of cultures of sputum may rob the patient of his chance of surgical cure. If on the basis of physical and x-ray examination the disease cannot be differentiated from pulmonary tuberculosis and a few specimens of sputum are negative, bronchoscopy should be performed without further delay. Inspection of the bronchi, if the patient's general condition admits it, yields valuable information that may determine not only the diagnosis but also how the case is to be managed. This is as true in pulmonary tuberculosis as it is in bronchiogenic carcinoma, since the presence or absence of endobronchial tuberculosis may alter the plans for collapse therapy. Hence, in either disease much may be gained by prompt bronchoscopic examination.

Griess, McDonald and Clagett,²⁶ in a study of the proximal extension of carcinoma of the lung in the bronchial wall, state that it is important for the surgeon to know what type of tumor he is dealing with in order to appreciate how close to the macroscopic lesion to make the operative incision. In an extremely limited number of cases it appears that on the average an adenocarcinoma extends much farther than does a squamous-cell epithelioma. With the skill of the modern bronchoscopist, biopsy can be done previous to the operation, and the surgeon, knowing what kind of lesion he is dealing with, can decide where to sever the bronchus. There are, of course, certain anatomic limits, and these probably accounted for the incision's passing through the carcinoma in some of the cases in this series. When dealing with adenocarcinomas the surgeon should, if anatomically possible, sever the bronchus more than 2 cm proximal to the gross limits of the lesion. If the tumor is a squamous-cell epithelioma, a safe distance to sever the bronchus is at least 1.5 cm.

Tinney, Moersch and McDonald²⁷ have reviewed 27 cases of neoplasm of the trachea seen at the Mayo Clinic since 1921. The lower third of the trachea is the region likeliest to be involved. Chills and fever, which frequently accompany bronchiogenic carcinoma, are less apt to occur in cases of tracheal tumor. Although routine roentgenographic studies may be of little importance in establishing the diagnosis, tomographic studies are often of considerable value. Roentgenograms taken after instillation of iodized oil into the trachea help fairly frequently to show the outlines of the lesion and often lead to the correct diagnosis. Sometimes the tumor may be seen on direct laryngoscopy. In most cases of carcinoma of the trachea, however, the diagnosis is dependent on bronchoscopic examination. The tumors in these 27 cases were divided into four distinct groups — squamous-cell carcinoma, 11 cases, cylindroma, 8 cases, adenocarcinoma, 6 cases, and hemangioendothelioma, 2 cases. Carcinoma of the

trachea offers an extremely difficult therapeutic problem, and no one form of treatment has been found satisfactory in all types of cases. Carcinoma situated in the upper portion of the trachea is best handled by means of tracheal fissure and destruction of the tumor by electrocoagulation, as advocated by Figg.²⁸ Carcinoma situated in the lower end of the trachea is best treated by electrocoagulation of the tumor through the bronchoscope. In a case of the series at the Massachusetts General Hospital in which adenocarcinoma of the trachea was extensive and could not be treated adequately by means of surgical diathermy the use of roentgen-ray therapy alone was followed by marked benefit. Although the life expectancy of most patients is between six months and one year, there are some notable exceptions. This is particularly true of tumors of the cylindroma group. One of the patients with this type of tumor died ten years after the diagnosis was made, apparently of an entirely unrelated disease. The other 7 were living and well when last heard from.

Hamartoma

McDonald, Harrington and Clagett²⁹ state that hamartoma of the lung has often been called chondroma. It is supposed to be the result of abnormal development of the bronchial anlage, — hence the name "hamartoma" (to err). The term was coined in 1904 by Albrecht, who stated

Hamartomata are tumorlike malformations in which occurs only an abnormal mixing of the normal components of the organ. The abnormality may take the form of a change in quantity, arrangement or degree of differentiation, or may comprise all three. The deduction to be drawn from histologic examination of these formations is that they have originated in an abnormal mixing of the elements or from disturbance of their development.

McDonald et al. have confined the use of the term "hamartoma of the lung" to a specific type of tumor that has a characteristic morphologic appearance, this is a solid tumor of the bronchus consisting of benign mesodermal and benign epithelial elements. Their paper is based on a study of 23 patients with hamartoma of the lung. Since the tumor is usually situated in the periphery of a pulmonary lobe, bronchoscopic examination is not of much value, but it should be done to rule out other pulmonary lesions. In 3 cases, the tumor was removed surgically, in the remaining 20, it was discovered at autopsy. These 20 cases were part of a consecutive series of 7972 cases in which autopsy was performed, the incidence of hamartoma of the lung in this series was 0.25 per cent. They conclude that this tumor occurs more frequently than has been recognized. It is strictly benign and only occasionally causes symptoms. In most cases the diagnosis has to be made by roentgenographic examination. A hamartoma should be suspected in every case of a solitary lesion of the lung. It frequently cannot be distinguished from other lesions of the lung until a

rules out tumor Exploratory thoracotomy, they conclude, is a procedure that is used too little and too late As regards safety and accuracy it is on a par with abdominal exploration

Clerf²⁰ believes that, since primary carcinoma frequently occurs in large bronchi that are accessible to bronchoscopic investigation, much aid has been given to the clinician by the bronchologist in its diagnosis There is no question in diagnosis if the classic infiltrating, ulcerated lesion is observed and a biopsy specimen can be secured Lesions occurring in an upper lobe "around the corner" or in subdivisions of the lower lobes or middle lobe present difficulties that must be promptly surmounted if any benefit is to be gained by establishing a positive early diagnosis Although the orifices of the upper lobe can be satisfactorily inspected by a telescopic obturator introduced through the bronchoscope, too often the lesion is beyond this point In these cases it is desirable to use a flexible, tipped aspirating tube attached to a collector so that secretions can be secured from "around the corner" and examined for neoplastic cells Careful attention to this will be rewarded by a fairly large number of positive findings A similar procedure can be instituted for subdivisions of the bronchi of the middle and the lower lobe The bronchologist also should observe whether there is narrowing, deformation, fixation or rigidity of a bronchus owing to neoplastic infiltration In the absence of biopsy material these findings are of great diagnostic significance Information concerning the mobility of the carina and the angle of division of the trachea is of importance to the thoracic surgeon

Miranda and Gonnella²¹ report a case of primary bronchial carcinoma with early cutaneous metastasis This is a rare site for metastatic lesions from bronchial carcinoma The patient was a man of thirty-seven who one month after recovery from pneumonia developed a chronic bronchitis with multiple cutaneous nodules over the chest wall A diagnosis of bronchial cancer was confirmed by bronchoscopy and by biopsy of the metastatic nodules

In a paper on the difficulties encountered in the differential diagnosis of bronchiogenic carcinoma, Bloch, Adams, Thorton and Bryant²² note the increased interest in carcinoma of the lung, which has led to much improvement in the diagnosis of pulmonary tumors With an ever better roentgen technic and by bronchoscopy, their differentiation from other involvements of the lungs seems to have become comparatively easy, and a diminishing number of patients with endobronchial cancer die because of an erroneous diagnosis Routine chest fluoroscopy in 15,000 patients showed that 91 (0.6 per cent) had intrathoracic neoplasms X-ray examination, which is indispensable for the discovery of a lesion, in no case offers a reliable differential diagnosis Although the bronchoscope is also indispensable, bronchoscopy also results in failure

to make a positive diagnosis when the tumor is inaccessible to the bronchoscope Bronchoscopy in early peripheral tumors, which according to Jaffe²³ constitute 13 per cent of the total incidence, is always negative In the absence of bronchoscopic findings, therefore, surgical exploration alone can lead to an acceptable diagnosis It should be undertaken even in early cases when there seems to be a strong enough possibility of neoplasm

In an analysis of 175 proved cases of bronchiogenic carcinoma, Holinger, Hara and Hirsch²⁴ have called attention to the United States Government's vital statistics on carcinoma in children and young adults In 1940, 1 death occurred in an infant under one year of age, 3 in those under two years, 2 in those under four years, 8 in children between five and nine years, 18 in those between ten and eighteen, 22 in those between fifteen and nineteen, 44 in persons between twenty and twenty-four and 38 in those between twenty-five and twenty-nine The disease is much more frequent on the right side than on the left, the ratio being 11.6 Bronchoscopic examination should be made in patients with obscure pulmonary disease as suggested by the history, symptomatology and x-ray findings Such symptoms as persistent cough, wheeze, unexplained hemoptysis and recurring or so-called "unresolved" pneumonia are all specific indications for bronchoscopy All too frequently, however, such indications are ignored and this examination is postponed or not considered The presumptive diagnosis of atypical pneumonia and the prolonged ineffective use of chemotherapy in an effort to clear a supposed pneumonia have been responsible for many delays in bronchoscopic examination In this series, six months or longer elapsed between the initial symptoms and bronchoscopy in 86 (50 per cent) of the patients In 14 (8 per cent) more than one year elapsed Among the latter group were 3 who had had a cough for more than ten years and could not accurately tell when their illness began The treatment of bronchiogenic carcinoma is primarily surgical Bronchoscopic treatment of bronchiogenic carcinoma is mentioned not as opposed to surgery but as a means of therapy in patients otherwise inoperable Although the results of endobronchial therapy by implantation of radon seeds or radium directly into the tumor have usually been palliative, clinical cures by the use of this method together with surgical diathermy have been reported

Pillsbury and Wassersug²⁵ have studied 12 proved cases of bronchiogenic carcinoma that were admitted to a tuberculosis hospital Patients with bronchiogenic carcinoma are occasionally admitted to a sanatorium, either for observation for tuberculosis or because a definite diagnosis of tuberculosis has already been made Since the clinical findings may be misleading, reliance must be placed on other diagnostic aids, such as x-ray examination, bronchoscopy and exploratory thoracotomy Bronchio-

genic carcinoma must be promptly differentiated from tuberculosis, since time and rest never cure a malignant growth. Waiting six weeks or longer for results of animal inoculation or tests of cultures of sputum may rob the patient of his chance of surgical cure. If on the basis of physical and x-ray examination the disease cannot be differentiated from pulmonary tuberculosis and a few specimens of sputum are negative, bronchoscopy should be performed without further delay. Inspection of the bronchi, if the patient's general condition admits it, yields valuable information that may determine not only the diagnosis but also how the case is to be managed. This is as true in pulmonary tuberculosis as it is in bronchiogenic carcinoma, since the presence or absence of endobronchial tuberculosis may alter the plans for collapse therapy. Hence, in either disease much may be gained by prompt bronchoscopic examination.

Griess, McDonald and Clagett,²⁶ in a study of the proximal extension of carcinoma of the lung in the bronchial wall, state that it is important for the surgeon to know what type of tumor he is dealing with in order to appreciate how close to the macroscopic lesion to make the operative incision. In an extremely limited number of cases it appears that on the average an adenocarcinoma extends much farther than does a squamous-cell epithelioma. With the skill of the modern bronchoscopist, biopsy can be done previous to the operation, and the surgeon, knowing what kind of lesion he is dealing with, can decide where to sever the bronchus. There are, of course, certain anatomic limits, and these probably accounted for the incision's passing through the carcinoma in some of the cases in this series. When dealing with adenocarcinomas the surgeon should, if anatomically possible, sever the bronchus more than 2 cm proximal to the gross limits of the lesion. If the tumor is a squamous-cell epithelioma, a safe distance to sever the bronchus is at least 1.5 cm.

Tinney, Moersch and McDonald²⁷ have reviewed 27 cases of neoplasm of the trachea seen at the Mayo Clinic since 1921. The lower third of the trachea is the region likeliest to be involved. Chills and fever, which frequently accompany bronchiogenic carcinoma, are less apt to occur in cases of tracheal tumor. Although routine roentgenographic studies may be of little importance in establishing the diagnosis, tomographic studies are often of considerable value. Roentgenograms taken after instillation of iodized oil into the trachea help fairly frequently to show the outlines of the lesion and often lead to the correct diagnosis. Sometimes the tumor may be seen on direct laryngoscopy. In most cases of carcinoma of the trachea, however, the diagnosis is dependent on bronchoscopic examination. The tumors in these 27 cases were divided into four distinct groups — squamous-cell carcinoma, 11 cases, cylindroma, 8 cases, adenocarcinoma, 6 cases, and hemangioendothelioma, 2 cases. Carcinoma of the

trachea offers an extremely difficult therapeutic problem, and no one form of treatment has been found satisfactory in all types of cases. Carcinoma situated in the upper portion of the trachea is best handled by means of tracheal fissure and destruction of the tumor by electrocoagulation, as advocated by Figi.²⁸ Carcinoma situated in the lower end of the trachea is best treated by electrocoagulation of the tumor through the bronchoscope. In a case of the series at the Massachusetts General Hospital in which adenocarcinoma of the trachea was extensive and could not be treated adequately by means of surgical diathermy the use of roentgen-ray therapy alone was followed by marked benefit. Although the life expectancy of most patients is between six months and one year, there are some notable exceptions. This is particularly true of tumors of the cylindroma group. One of the patients with this type of tumor died ten years after the diagnosis was made, apparently of an entirely unrelated disease. The other 7 were living and well when last heard from.

Hamartoma

McDonald, Harrington and Clagett²⁹ state that hamartoma of the lung has often been called chondroma. It is supposed to be the result of abnormal development of the bronchial anlage, — hence the name "hamartoma" (to err). The term was coined in 1904 by Albrecht, who stated

Hamartomata are tumorlike malformations in which occurs only an abnormal mixing of the normal components of the organ. The abnormality may take the form of a change in quantity, arrangement or degree of differentiation, or may comprise all three. The deduction to be drawn from histologic examination of these formations is that they have originated in an abnormal mixing of the elements or from disturbance of their development.

McDonald et al. have confined the use of the term "hamartoma of the lung" to a specific type of tumor that has a characteristic morphologic appearance, this is a solid tumor of the bronchus consisting of benign mesodermal and benign epithelial elements. Their paper is based on a study of 23 patients with hamartoma of the lung. Since the tumor is usually situated in the periphery of a pulmonary lobe, bronchoscopic examination is not of much value, but it should be done to rule out other pulmonary lesions. In 3 cases, the tumor was removed surgically, in the remaining 20, it was discovered at autopsy. These 20 cases were part of a consecutive series of 7972 cases in which autopsy was performed, the incidence of hamartoma of the lung in this series was 0.25 per cent. They conclude that this tumor occurs more frequently than has been recognized. It is strictly benign and only occasionally causes symptoms. In most cases the diagnosis has to be made by roentgenographic examination. A hamartoma should be suspected in every case of a solitary lesion of the lung. It frequently cannot be distinguished from other lesions of the lung until a

specimen of the tumor is examined microscopically. Treatment consists of excision of the tumor. One should try to conserve as much pulmonary tissue as possible.

Tuberculosis

Clerf²⁰ believes that credit must be given to bronchoscopy for the discovery that certain signs and symptoms in tuberculous patients and certain complications following the surgical treatment of tuberculosis are the result of tuberculous involvement of the larger bronchi by infiltrative, ulcerogranulomatous or cicatricial lesions. It is in this group that bronchoscopy plays a definite part in diagnosis as well as in treatment. Inspection of the tracheobronchial tree is usually adequate to determine the presence of infiltrative and ulcerogranulomatous lesions, and biopsy is therefore advised against unless there is considerable evidence to support the belief that carcinoma is present. It is important to discover the presence of obstructive lesions in a bronchus so that the clinician or surgeon may take this into account when contemplating some form of collapse therapy.

Wilson³⁰ has attempted to correlate the clinical and pathological findings in tracheobronchial tuberculosis. Endobronchial tuberculosis has been found in 10 to 15 per cent of patients at the time of sanatorium admission. The author advises that no attempt be made to dilate fibrotic stenosis; instead, he suggests thoracoplasty or pneumonectomy. He opposes biopsy because of the possibility of initiating ulceration. He advises treatment with silver nitrate every two weeks until healing ensues, following which the intervals between applications should be gradually lengthened. If no response is obtained over a reasonable time, pulmonary resection is advised.

Chamberlain,³¹ in a discussion of lobectomy versus thoracoplasty in the treatment of tuberculosis, repeatedly states that endobronchial tuberculosis is present in all cases of tuberculosis with cavitation. Although clinically physicians have been aware of endobronchial tuberculosis only in the last ten years, it has always been present, though it may have been beneath the mucosa or just beyond the view of the bronchoscopist. The significance of this complication is directly proportional to the kind of endobronchial lesion, the size of the bronchus involved and the degree of obstruction. Obviously, a small submucous tubercle is not so serious as an ulcerative lesion that circumscribes and almost completely obstructs a large bronchus. An ulcerative endobronchial lesion of moderate or extreme severity implies severe damage distal to it in the form of obstructive emphysema, suppuration, atelectasis or tension cavities. A definitive form of therapy is therefore indicated if one or more of these complications exist. Thoracoplasty had met with considerable success before physicians were aware of the

presence of endobronchial tuberculosis, and they now intentionally do thoracoplasties in cases with certain types of lesions in the major bronchi (visible at bronchoscopy), with good results as reported by Alexander, Tuttle, Chamberlain, and Gordon.³² It must also be kept in mind that in every case of tuberculosis there are both obstructive (endobronchial disease) and overdistention types of emphysema, which are directly proportional to the amount and duration of the tuberculosis. Endobronchial tuberculosis is present in all cases with cavitation, and its significance is essentially dependent on the degree of bronchial obstruction, which may cause obstructive emphysema, suppuration, atelectasis and tension cavities. Thoracoplasty is successful in 75 per cent of the cases in which the diseased bronchus is visible by bronchoscopy.

In a discussion of pulmonary resection in the treatment of tuberculosis, Overholt and Wilson³³ point out that bronchoscopy has revealed the presence of bronchial tuberculosis in many patients. This has helped to avoid many of the mistakes made in the earlier selection of cases and to plan the proper operation and the extent of resection. Tuberculous bronchitis, either active or inactive, is not itself a contraindication to resection even if it has to be traversed during the procedure. On the contrary, this complication is often an indication for resection.

Stone,³⁴ in a discussion of the clinical aspects of endobronchial tuberculosis, states that the lung specialist can never consider himself adequately trained until he has mastered the art of bronchoscopy. Furthermore, bronchoscopy will never render its maximum service to medicine until it is embraced by the man to whom it rightfully belongs—the specialist in chest diseases. The incidence of endobronchial tuberculosis obviously varies with the zeal as well as with the skill of the operator. The diagnosis of endobronchial tuberculosis can be definitely made only when it can be visualized by the bronchoscopist. The chief symptoms in this group are a localized wheeze and loud auscultatory rhonchi. Next to wheezing and rhonchi is the completely collapsed lung or the so-called “opaque” unexpandable lung.

Postoperative Use of the Bronchoscope

Clerf³⁰ points out that an extremely simple method of removing excessive secretions in the tracheobronchial tree after an operation consists of the employment of a catheter introduced into the trachea and attached to a mechanical apparatus. Patients who cannot be relieved by these simple methods should be aspirated by bronchoscopy.

Aronovitch³⁵ calls attention to the formation of a mucous plug following operation, with the familiar picture of fever, shallow respirations, cyanosis and chest pain. Sometimes exceedingly simple procedures such as a slap on the back, directing the patient to cough hard or placing him in the proper

position dislodge the plug. If after twenty-four hours these measures fail when used in combination with adrenalin or ephedrine, aspiration should be performed.

Lundy and his associates³⁶ in a report on anesthesiology have again emphasized the importance of bronchoscopic aspiration at the end of operation. Such an operation is generally acknowledged to be valuable and has proved to be so in their hands, especially in intrapulmonary operations.

In the surgical treatment of bronchiectasis, Clagett³⁷ uses bronchoscopy immediately after operation to clear the bronchial tree.

Lung Abscess

According to Clerf,²⁰ in the earlier days of bronchoscopy before much progress had been made in the successful treatment of pulmonary abscess by thoracic surgery, it was not unusual to practice bronchoscopic aspiration in these cases. The fundamental principle was a sound one — namely, that the abscess would undergo resolution if adequate drainage of pus could be established and maintained. In a certain number of cases of acute pulmonary abscess one can obtain satisfactory results if drainage can be improved by bronchoscopic aspiration with curved, flexible, tipped aspirating tubes and the employment of shrinking solutions. It is believed inadvisable, however, to continue bronchoscopic treatment for more than two or three weeks unless continuous improvement is observed. If the temperature does not promptly return to normal after several aspirations and definite improvement is not shown by roentgen-ray examination, bronchoscopic treatment should be discontinued.

No report can be given on the newer drugs, notably sulfonamides and penicillin employed bronchoscopically. It is believed that these exert little effect if introduced into the abscess cavity through the bronchoscope. In chronic abscess and in cases in which there is a question of new growth complicated by abscess, a diagnostic bronchoscopy is indicated. Cases of endobronchial foreign body, either exogenous or endogenous, complicated by pulmonary abscess have been recorded, and a number of cases of unsuspected carcinoma of the bronchus have been treated surgically as cases of pulmonary abscess, with unfavorable results.

Smyth and Billingslea,³⁸ in a review of the literature, have found reference to 31 cases of lung abscess treated with penicillin. Thirteen have shown complete recovery, 8 have shown satisfactory improvement, and in 10 cases there was either no change or death occurred. In a study of 4 of their own cases, these authors state that the long-continued use of penicillin has resulted in the control of the surrounding pneumonitis in all 4 cases and has permitted the healing of the abscess cavities in 3 of them. They are of the opinion that if lung abscesses are recognized early and are vigorously

treated by long-continued penicillin administration, there will be an appreciable reduction in the morbidity and mortality from this disease.

Valle³⁹ has analyzed 244 cases of lung abscess. The differentiation of simple lung abscess and carcinoma is difficult because there is often a combination of the two resulting from an infection of the carcinoma. The x-ray picture of bronchiogenic carcinoma often shows atelectasis of one lobe and a poorly outlined shadow. Some cases of carcinoma develop pleural fluid in which carcinoma cells can be detected. The author believes that the best means of differentiating the two is bronchoscopy, which in bronchiogenic carcinoma generally reveals the growth to be blocking the bronchus, from which a biopsy can be taken. Sometimes the bronchus can be seen to be compressed from without. In a few cases the tumor is out of reach of the bronchoscope and an accurate diagnosis cannot be made until an exploratory thoracotomy has been performed. As regards etiology and pathogenesis, Valle found that lung abscesses developed in 41 cases after tonsillectomy under anesthesia and in 27 after abdominal operation under general anesthesia. In this connection he states that Myerson subjected to bronchoscopy a number of patients who had had tonsillectomies performed under general and local anesthesia and found blood and mucus in the lower bronchi in 90 per cent of the cases with general anesthesia, but in a much lower percentage among those having local anesthesia and the cough reflex present. Valle and his associates consider bronchoscopy one of the most important features in the diagnosis and treatment of lung abscess. Of 80 patients treated by bronchoscopy alone, 47 were improved. As a diagnostic procedure it is extremely useful in localization of the abscess by revealing which bronchus is the source of pus. As a part of the treatment bronchoscopy is much used. Sometimes the draining bronchus becomes plugged, and by introducing the flexible suction tip into the bronchus the mucous plug is removed and drainage promoted. Patients who are confined to bed can often be so greatly improved by several bronchoscopic aspirations that the later surgical drainage becomes less hazardous. Valle considers bronchoscopy imperative whenever aspiration of a foreign body into the bronchial tree is suspected.

Sweet⁴⁰ has analyzed the cases of lung abscess from 1938 to 1942 at the Massachusetts General Hospital. He notes the significant fact that the total duration of the disease in many of the spontaneous-cure group was of surprising length. Although 9 patients recovered in three months or less, the disease lasted for three to six months in 8 cases and from six to twelve months in 6. Two patients recovered after the expiration of one year. The use of sulfonamide chemotherapy produced no material change in the results in this series. Although lung abscess continues to be a serious disease, there

has occurred over the last ten or more years an encouraging increase in the number of cures and a gratifying reduction in the mortality rate

Hemoptysis

Adams and Ficarra⁴¹ note that "hemoptysis" is a term specifically applied to bronchopulmonary hemorrhage. Before bleeding emanating from the nose or mouth can be definitely called hemoptysis, all forms of pseudohemoptysis must be eliminated. The types of bleeding most frequently confused with hemoptysis are hematemeses and epistaxis. Inspection of the nasal and oral pharynx will exclude epistaxis and bleeding from the pharynx, the back of the nose, the tonsils, teeth, gums, tongue and mucous membrane of the buccal cavity. The differential diagnosis between hemorrhage from the alimentary canal and bronchopulmonary hemorrhage is often difficult. The majority of causes for hemoptysis can be classified in the following groups: tuberculosis of the lung and bronchi, bronchiectasis, abscess of the lung, lobar pneumonia, infarction of the lung, carcinoma of the lung, traumatic lesions of the chest and congestive heart failure. Less frequent etiologic agents are chronic bronchitis, diseases of the larynx, adenoma of the bronchus, gangrene of the lung and mediastinal tumors. The diagnosis can be made from the history and physical findings, roentgen-ray studies, bronchoscopy and laboratory data, including sputum studies. Bronchoscopy as a therapeutic measure is useful when bleeding has been so extensive as to cause bronchial obstruction or atelectasis.

Complications

Abbott and De Oliveira⁴² have reported 4 cases of pneumothorax occurring in conjunction with bronchoscopy and 1 case coincident to esophagoscopy. In the cases reported no major bronchi suffered direct injury. They describe the phenomenon not as a complication of bronchoscopy but rather as an indirect hazard of the coughing paroxysm subsequent to endoscopic manipulation.

(To be concluded)

CASE 32271

PRESENTATION OF CASE

A sixteen-year-old schoolgirl entered the hospital because of headache, photophobia, diplopia and mild tinnitus.

Thirty days before admission, during a lecture, the patient had a sudden frontal headache, which was the first severe headache she had ever had. Subsequently there were severe headaches lasting about five minutes each, with intervals of from five to ten minutes between them. The pain started in the forehead and radiated down the neck, shoulders and arms. Each attack was accompanied by a generalized sensation of warmth. A dull constant ache gradually developed between attacks. Twenty days before admission, glasses were prescribed. Four days later the patient noticed blurring of vision, and on the following day she felt nauseated and at the same time began to have double vision. On the next day there was an episode of vomiting, the only one during this illness. One week before admission she felt dizzy and unsteady on standing. Buzzing in the ears, excessive lacrimation and photophobia developed in the last four days.

On physical examination the patient was alert and oriented. The pupils were equal and measured 4 mm. They did not react to light but did react to convergence. There was a 15° limitation of abduction of the left eye. The diplopia disappeared when the patient looked 10° to the right. There was limitation of upward gaze, with the left eye elevating 10 to 15° better than the right. On extreme supraversion there was a strong, sudden convergence. The visual fields were normal. There was papilledema of 1 or 2 diopters on the right and 2 or 3 diopters on the left. There was slight vertigo. Flexion of the neck was moderately limited and painful. There was a positive Kernig sign. The tendon, abdominal and plantar reflexes were normal. Sensation was normal.

The temperature was 99°F, the pulse 82, and the respirations 22. The blood pressure was 115 systolic, 75 diastolic.

There were 14.5 gm of hemoglobin per 100 cc of blood. The white-cell count was 10,300, with 72 per cent neutrophils. The urine had a specific gravity of 1.021. There was a + test for albumin, and the sediment contained 20 white cells and a rare red cell per high-power field. The spinal fluid was under an initial pressure equivalent to 260 mm of water, which fell to 150 mm with removal of 10 cc. The fluid was clear and contained 124 red cells, 6 lymphocytes and 1 polymorphonuclear cell per cubic millimeter. The total protein was 36 mg per 100 cc. The electroencephalogram was moderately abnormal, with suspicious activity on the left side that was thought to be slightly more marked toward the occiput, although a positive localization was not possible. X-ray examination of the skull was negative. The blood and spinal-fluid Hinton and Wassermann tests were negative.

On the fourth hospital day bilateral occipital burr holes were made. Immediately after operation, the patient was restless, had a severe headache and did not recognize people. Four hours later she suddenly stopped breathing.

DIFFERENTIAL DIAGNOSIS

DR. DAVID COGAN: As I read over this record, it seemed to me to include a number of red herrings, and I should like to go over it sequentially and analyze the symptoms and findings, eliminating the insignificant ones.

In the first place, we are told that this patient, a sixteen-year-old girl, had sudden spontaneous headache. In itself, that symptom suggests a rupture of a congenital aneurysm. Ordinarily aneurysm produces headaches that have a sudden onset, but I have seen patients in whom the recurrences took place at reasonably long intervals—a matter of days, not every five or ten minutes as in this case.

Casting about for other causes of intermittent severe headache, one must think of intermittent block of the aqueduct—something in the region of the anterior midbrain. In that connection it would be interesting to know if movements of the head precipitated the headache or relieved the headache, as it sometimes does when there is a ball-valve obstruction of the aqueduct.

The pain started in the forehead and radiated down the neck, shoulders and arms, all of which suggests nothing to me. The generalized sensation of warmth with the attacks is of interest. If there were other corroborative evidence, such a sensation would be suggestive of a diencephalic lesion. The rest of the history, including a note about vomiting and dizziness, is compatible with increased intracranial pressure, all of which, except for the photophobia, I do not know how to interpret.

Physical examination disclosed something definite: the pupils were equal, measured 4 mm and did not react to light but did react to convergence. These

were not Argyll-Robertson pupils because of their size. A pupil of 4 mm is normal for a sixteen-year-old person. If the pupils were typically Argyll-Robertson, they would be miotic, and if large they would be of unequal size and irregular. These

give weakness of the external rectus muscle, presumably through involvement of the sixth nerve as it angulates over the sphenoidal ridge.

Limitation of upward gaze is significant and goes with the type of pupils that she had, under the

FIGURE 1

normal-sized pupils, which reacted for near vision but not for light, are strongly indicative of a lesion in the region of the superior colliculus.

There was a 15° limitation of abduction of the left eye, which I assume was due to paralysis of the external rectus muscle, since we are told that diplopia disappeared when the patient looked 10° to the right. But in the presence of increased intracranial pressure an altered paralysis of the rectus means nothing so far as localization is concerned. Increased intracranial pressure alone can

heading of Parinaud's syndrome, which is pathognomonic of a lesion in the region of the superior colliculus. The paralysis of upward gaze and the pupillary signs fit into the syndrome. The statement that the left eye elevated 10 to 15° better than the right is confusing to me, especially since the diplopia disappeared when the patient looked just 10° to the right. If the left eye showed a difference of 15° somewhat above the midline, I should expect vertical diplopia in the horizontal position.

I am going to have the temerity to say that I think that observation may have been erroneous

On extreme supraversion there was strong sudden convergence. That means on attempted extreme supraversion, because the patient had weakness of upward gaze. Sudden convergence is a reaction that occurs in people who attempt to do something that they cannot do. This patient attempted in vain to look up, and convergence is not an infrequent reaction under those circumstances and has no localizing significance.

The papilledema goes with increased intracranial pressure, which is also compatible with a lesion in the region of the superior colliculus obstructing the aqueduct. The slight vertigo, the flexion of the neck and the positive Kernig sign, I interpret as resulting from the increased intracranial pressure and as having no further significance. There was no evidence of meningitis or of tumor of the posterior fossa, which might cause these signs.

The neurologic examination was negative except for the eyes. The laboratory data are not helpful. The urine was not a catheterized specimen, and I assume that it was not significant. I was surprised that a lumbar puncture was done, in view of the apparent increased intracranial pressure, which was evident in the papilledema. The fluid was clear and contained 131 cells per cubic millimeter. I have been looking for other evidence of aneurysm, but in view of the fact that this fluid was not xanthochromic and the protein was normal, I shall interpret the cells as being incidental to the puncture. The electroencephalogram I take to be equivocal.

In summary, I believe that the signs point to a lesion in the region of the superior colliculus with increased intracranial pressure and no definite indication of the nature of the lesion, but in view of the increased intracranial pressure I think that the likeliest diagnosis is a tumor. The most frequent tumors of this region are pinealoma, teratoma of the pineal body, tuberculoma and glioma of the mesencephalon. In the cases that I have seen with this general syndrome, however, there were two patients with aneurysm who never came to autopsy, so that I do not know where the aneurysm was. But I am humbled in the suggestion that it was a tumor by the fact that there were these cases of aneurysm.

We are told that occipital burr holes were made, I am at a loss to understand why, since there was no evidence of subdural hematoma, and I am wondering if the burr holes were made preliminary to an air injection and why the results of this injection were not described. Certainly air injection in this case would have been most helpful, particularly air in the region of the third ventricle.

DR CHARLES S KUBIK: The lateral ventricles were tapped, but no air was put into them.

DR COGAN: Death I assume to have been caused by a pressure cone. At least one other patient seen

in this hospital four or five years ago with a pinealoma met death in a similar fashion from a pressure cone.

CLINICAL DIAGNOSIS

Midbrain tumor

DR COGAN'S DIAGNOSES

Lesion in the region of the superior colliculi (probably tumor, possibly aneurysm)

Pressure cone as cause of death

ANATOMICAL DIAGNOSIS

Pinealoma.

PATHOLOGICAL DISCUSSION

DR KUBIK: In the region between the quadrigeminal plate and the splenium of the corpus callosum, where the pineal gland would normally be situated, there was a soft, friable tumor mass, 2.5 cm

FIGURE 2

to 3.0 cm in diameter, which extended forward into the third ventricle. In this position it was situated between and invaded the posterior portions of the optic thalami. It also extended downward, invading the superior and inferior colliculi and the upper part of the tegmen of the pons. The aqueduct was partly occluded, and as a result the lateral ventricles were enlarged to three or four times their normal size (Fig 1).

In cases of increased intracranial pressure in which death results from respiratory failure, a cerebellar

pressure cone is usually found at autopsy. The lower poles of the cerebellum and the medulla are forced downward into the foramen magnum, the herniated portions of the cerebellum forming a wedge that compresses the medulla and obliterates the blood supply of the respiratory center. In this case there was no pressure cone. It is possible, I suppose, that a high and rapid rise in intracranial pressure produces a similar effect on the respiratory center and results in death before any appreciable herniation of the cerebellum has taken place.

The tumor was composed of medium-sized, rounded and polyhedral pyramidal cells, some of which had well defined short cytoplasmic processes (Fig 2). They bore a close resemblance to cells of the normal pineal gland. Scattered among the tumor cells were a few lymphocytes. In this respect the tumor differed from some of the other pinealomas examined here, in which there were large numbers of lymphocytes and plasma cells, not only in the tumor but also in the adjacent subarachnoid and perivascular spaces.

CASE 32272

PRESENTATION OF CASE

A thirty-three-year-old married woman, a factory employee, entered the hospital because of intermittent fever.

Two years and eight months before admission the patient started working in a war plant. She was not exposed to any toxic substances. Six months later she began to have frequent colds and bouts of hoarseness. On one occasion she had a severe sore throat, with a temperature of 104°F lasting for several days. During the succeeding six months she lost weight, had a poor appetite, and a dry hacking cough and worked only part time. She began to run an intermittent fever of 101 to 102°F. At that time a chest film was taken, and blood tests were performed, she did not know the results. All her teeth were removed. In the two years preceding admission she was constantly fatigued and had frequent chills and fever, usually accompanied by sweats at night. She lost 60 pounds. Her condition was studied at a community hospital for five days, but no diagnosis was made. While in the hospital she developed a boil on the buttock, which was lanced. At home she had three more boils, which ruptured and drained spontaneously. During the two months before admission a dull ache developed along the left costal margin in the midaxillary line. There was a sharp pain on coughing, with occasional vomiting after coughing. With the appearance of the ache, the temperature rose to 104°F and remained elevated. Violent chills developed, and were accompanied by throbbing frontal headaches. During the chills the hands became white, and the fingertips blue. She fainted twice. During this illness, the menstrual

periods gradually shortened to one day, and the flow was scanty. There were no other past illnesses. A former landlady with whom the patient had lived for two years had had cancer and possibly tuberculosis.

Fifteen and thirteen years prior to admission the patient underwent cesarean sections because of pelvic deformity from an automobile accident in childhood. The right ovary was removed at the second operation. Following this procedure a large abscess developed in the wound, taking four months to heal. Six years before admission she had an episode of severe lower abdominal pain and a vaginal discharge lasting four days.

On physical examination the patient was flushed and feverish. The heart sounds were forceful. There was a Grade II apical systolic murmur transmitted to the axilla and a Grade II pulmonic systolic murmur. The pulmonic second sound was greater than the aortic. Breath sounds, fremitus and voice sounds were absent over the entire left chest below the level of the eighth thoracic vertebra. The left diaphragm did not move. The whole area was tender. The left side of the abdomen was tender, with marked sensitivity in the upper quadrant. A mass in this region seemed to move on inspiration and was exquisitely tender. There was considerable voluntary spasm. The left vaginal vault was tender.

Examination of the blood showed a red-cell count of 3,100,000, with a hemoglobin of 8.5 gm. The white-cell count was 20,500 with 94 per cent neutrophils and a marked shift to the left. The urine had a specific gravity of 1.003. There was a ++ test for albumin. The sediment contained 200 to 400 white cells in clumps per high-power field.

X-ray examination showed the right side of the chest to be normal. The left leaf of the diaphragm was elevated and limited in motion. There were linear areas of atelectasis above the diaphragm. The heart was normal. A large tumor mass in the left upper quadrant, measuring approximately 10 by 14 cm in diameter, seemed to occupy the site of the left kidney. The corrected sedimentation rate was 13 mm per minute. The tuberculin test was positive in a dilution of 1:100,000. A phenol-sulfonephthalein test showed 85 per cent excretion of the dye in two hours. No dye was excreted by the left kidney after intravenous pyelography. Abundant beta-hemolytic streptococci were cultured from the urine. The blood culture was negative. Serum agglutination tests for the typhoid-paratyphoid group of organisms and for *Brucella* were negative. An electrocardiogram was normal.

An operation was performed on the sixth hospital day.

DIFFERENTIAL DIAGNOSIS

DR WYLAND F. LEADBETTER. We are dealing with the illness of a thirty-three-year-old woman,

which presumably began about two years before admission to the hospital. The illness was characterized by intermittent attacks of chills and fever, as well as loss of weight and appetite, and was punctuated by at least one episode of severe sore throat, with a temperature of 104°F. At one time all her teeth were removed, presumably following search for foci of infection. She developed a series of boils, which probably have no bearing on the subsequent course of the case, although this fact should be kept in mind. She was admitted to a hospital for five days during a period when she was having chills and fever, but no explanation for the symptoms was found. She had at times had a dry cough, not a productive cough, if one can trust the history. Two months before admission to this hospital she had localizing signs for the first time. She began to develop pain and discomfort in the left upper abdomen and left flank, and reported the development of a persistent temperature, which was stated to have reached 104°F and to have remained at that level. On admission to the hospital she was obviously very sick. There was absence of breath sounds in the left chest below the eighth rib. There was tenderness in the left upper abdomen and flank, and an obvious mass could be felt in this area. She had a rather marked secondary anemia, and a white-cell count of 20,500, with 94 per cent neutrophils. The urine showed a specific gravity of 1.003, which I think is of no significance, because we do not know under what conditions it was obtained. There was a ++ test for albumin, and the urinary sediment showed 200 to 400 white cells per high-power field — in other words, there was a marked pyuria.

An x-ray film showed a clear right chest, an elevation of the diaphragm on the left, with limitation of motion, and evidence of atelectasis in the left lower lung, presumably due to pressure from the mass below the diaphragm. A plain x-ray film of the abdomen is said to have shown a large tumor mass measuring 10 by 14 cm. I should think that that was not an unusually large tumor mass, particularly if it was associated with the kidney. A tuberculin test was positive in a dilution of 1:100,000. A phenolsulfonephthalein test showed 85 per cent excretion in two hours, which I presume was considered normal. An intravenous pyelogram showed no dye coming through the left kidney. I think that we can assume that the right kidney was normal. Interestingly enough, abundant beta-hemolytic streptococci were cultured from the urine. Although such a finding is not rare, it is difficult to explain this woman's symptoms on such a basis. A blood culture was negative. I assume that the question of subacute bacterial endocarditis came up. The negative culture may be considered to rule it out. Agglutination tests for typhoid, paratyphoid and brucellar organisms were negative. The electrocardiogram was normal.

On physical examination the patient had evidence of systolic apical and pulmonic murmurs. In view of the long illness and secondary anemia, I assume that those could be considered to be benign murmurs and that increased intrapulmonic pressure might have caused accentuation of the pulmonic second sound.

Before we go any farther I think that it would be of interest to see the x-ray films. It should be quite simple to arrive at a definite diagnosis in this case, provided that there is a good pyelogram. We can assume that the difficulties of this patient were localized in the left kidney because of the mass in that region, the fever, the elevated white-cell count, the pyuria and the nonfunctioning left kidney.

DR JAMES R. LINGLEY: This film shows the high left diaphragm. The density in the lower lung field is, I think, quite consistent with atelectasis. This plain film of the abdomen shows a large mass on the left side, which has the shape of the kidney, and on the intravenous pyelogram there is evidence of excretion on the right side and the pelvis and calyces on that side are somewhat elongated. On the left side there is no evidence of excretion.

DR LEADBETTER: There is no evidence of a perinephric mass?

DR LINGLEY: No.

DR LEADBETTER: A retrograde pyelogram of the left kidney would have been helpful, because there are a good many possibilities. I think that it is impossible to arrive at a specific diagnosis other than to assume that the patient had an enlarged left kidney, pyuria, with an elevated temperature, and presumably pyonephrosis. This was a long-standing illness, and if we assume that the illness over a period of two years was due to infection in the left kidney, extension to the perinephric tissues or the development of an actual perinephric abscess would not be unusual at this late date. However, I think that the x-ray film does not suggest any evidence of a perinephric abscess, and we are forced to assume that she had a pyonephrosis and preceding that a pyelonephritis that was active at intervals, at least over a two-year period. The possibility of a carbuncle of the kidney should be mentioned, I suppose, but I should stress the fact, if the culture report is to be trusted, that beta-hemolytic streptococci would probably not cause an abscess so frequently as staphylococci, and I believe that this woman probably did not have a carbuncle of the kidney or a perinephric abscess.

Assuming that the woman did have a pyonephrosis, one must trace the development of the process and try to determine why she ended up with this particular picture. Infection of both kidneys is usually the result either of introduction of infection from below or of transmission of infection to the kidneys by way of the blood stream. We know that when an infection persists in the kidney it is usually the result of obstruction to the outflow of

urine from that kidney. I therefore think that we can assume that this woman had some sort of obstructive lesion involving the ureteropelvic junction, the ureter or the terminal portion of the ureter in the bladder, and I see no way of arriving at a definite opinion regarding the location of the obstruction. Obstruction is most frequent at the ureteropelvic junction. On the other hand several things in the history suggest another point of obstruction in this case. Fifteen and again thirteen years before admission to the hospital she had cesarean sections, and following the last section, when an ovary was removed, the wound became infected and drained for four months. We have no record of whether the drainage contained purulent material or urine, but it is possible that this woman had an inflammatory reaction in the pelvis, with periureteritis, which subsequently caused constriction of the lower ureter. Going back still farther in the history we find that as a child she was injured in an automobile accident and presumably suffered a fractured pelvis. There may have been a retroperitoneal hematoma at that time which involved the ureter. Possibly there may have been a congenital stricture of the ureter.

Finally, one other diagnosis that should be considered is tuberculosis, because it is not unusual for a chronic renal tuberculosis to result in stricture of the ureter as an extension of a tuberculous pyelonephritis or for a tuberculous kidney to be infected secondarily with other organisms. There is no way of determining this from a standpoint of reasoning, and I simply point out the fact that there are several possibilities: stricture of the ureter on the basis of injury, on the basis of old infection, possibly on the basis of tuberculosis or on the basis of congenital

abnormality of the ureteropelvic junction. I think that the final episode was the development of a pyonephrosis in which beta-hemolytic streptococci may have been the infecting organisms.

CLINICAL DIAGNOSIS

Carbuncle of kidney

DR. LEADBETTER'S DIAGNOSIS

Pyonephrosis, left

ANATOMICAL DIAGNOSES

Tuberculosis of kidney

Tuberculous peritonitis

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY. The preoperative diagnosis was a carbuncle of the kidney. An exploration of the kidney was done, extensive perirenal infection was found and drainage was instituted. At a subsequent operation an attempt was made to remove the kidney, but the disease had already progressed beyond practical operability. It was necessary to remove a considerable portion of the diaphragm and the adrenal gland on that side. The kidney and surrounding tissues showed massive tuberculosis. There was no gross evidence of abscess formation. The patient died some weeks later of tuberculous peritonitis.

DR. LEADBETTER. I should like to point out that chills and fever are extremely rare in renal tuberculosis. In fact it is the exception rather than the rule for a patient with pure renal tuberculosis to have fever of any considerable degree.

POLITICS AND THE PUBLIC HEALTH

THE administration of a department of health in any large community has become a highly complex problem. It is a professional task requiring considerable training and experience in many and varied fields. The need for such training has given rise to several professional schools in which the curriculum is designed especially for graduates in medicine and for others interested in certain narrower technical fields to prepare them for a career in the control and prevention of disease.

In recent years some legislative bodies have become cognizant of these needs for training and experience in the protection of the public health. They have therefore incorporated into the laws

governing the choice of public-health administrators certain provisions intended to safeguard the public against arbitrary appointments made solely for political expediency rather than for the health and welfare of the people. The requirements in training and experience for these positions are usually made rather exacting, and provisions are also included for consultations with leading authorities within the profession for advice and guidance.

The maintenance and advance of public health is in itself a potent political weapon and in the hands of capable and high-minded chief executives has been encouraged and used to the best advantage. This has meant a careful search for the best talent available, as well as the vigorous support of the chosen servants in the fulfillment of their tasks. It has also been necessary to resist all temptation to yield to pressures to choose politically favored but unqualified or mediocre candidates instead of those best qualified for the task. The recognition of these principles has resulted in the development of outstanding departments of public health in several states and cities, and these in turn have led the country in advancing the health and welfare of its citizens.

Unfortunately, changes in political tides have often brought with them elected representatives of the people who place political interests ahead of the public health and welfare. In so doing, they flout the advice and counsel of leaders in the field of public health and choose their supporters or friends to head the health services of their communities. This has invariably resulted not only in an arrest of progress but also in a deterioration, if not destruction, of the work so tediously and conscientiously built up by their capable predecessors. Not so many years ago Massachusetts went through an experience of this sort, and recently the newly elected mayor of New York City, ignoring and brushing aside the judgment and recommendations of his city's and some of the country's leading authorities, made a purely political appointment, which certainly cannot be construed as following the intent of the law concerning training and experience in public health. It is a great pity that the devoted and conscientious labors that his predecessors in office put into the

maintenance of a high standard in personnel and in performance in New York City's health services should be treated with so little respect and consideration

In New York City, the forces of medical authority and of general opinion in the field of public health sometimes break through political pressures, at least to the point of being articulate in their criticism and in placing the facts before the public. These combined forces resulted in the resignation of the mayor's first appointee, and another attempt was made to obtain a suitable candidate for the position. It was hoped that this time the carefully considered opinion of a committee of recognized experts would not be flouted. But politicians, when they are obviously in error, have an uncanny way of compromising by substituting subservient mediocrity for competent but militant and progressive leadership. Such apparently was the case in the mayor's final choice.* How this will affect the high quality of health services to which the people have become accustomed and what this implies in terms of the health of the people of America's largest city, remain to be seen.

AVITAMINOSES AND HYPOPROTEINEMIA IN STARVATION

WAR is invariably followed by famine, and advantage of this unfortunate by-product has already been taken by a number of physicians and biochemists interested in nutrition. A few preliminary studies of starvation in occupied countries have appeared,^{1, 2} and it is hoped that the complete reports will soon be published. Severe starvation in prison camps was seen throughout the world and is the subject of a report by Butler, Ruffin, Sniffen and Wickson,³ who examined civilians after their release from Japanese camps. These reports contain a number of interesting and significant observations.

As would be expected, loss of weight was usually severe. For example, Butler et al. reported average losses of 30 pounds for women and 50 pounds for men after three years of internment. In Rotterdam, the average weight loss was 25 pounds.¹

Evidence of gross manifestations of vitamin deficiency was surprisingly uncommon, in fact, with the exception of occasional reports of specific deficiencies, such as those described by Butler et al., they were not observed. Several explanations for this have been suggested. One is that most of the food eaten was unrefined. Thus, in Europe, bread made from coarse flour that contained an assortment of the components of the vitamin B complex, including thiamine, was the staple. On the contrary, polished rice was a principal article of diet of the Japanese prisoners, which may have accounted in part for the evidence of thiamine deficiency that was observed in this group. It is probable that the appearance of a greater number of symptoms and signs of deficiency was prevented by the low caloric value of the food eaten, with an attendant reduction in metabolism, which, in turn, decreased the vitamin requirements.

The incidence of so-called "hunger edema" was high in all the reports. Undoubtedly, in many cases this was due to hypoproteinemia and a consequent reduction in serum osmotic pressure, and in others, especially those studied by Butler et al., to thiamine deficiency. Nevertheless, a significant number of persons with edema were observed in whom the serum protein concentrations were normal and no evidence of thiamine deficiency was apparent. This was true in Holland, where both the albumin and the globulin were determined.¹ In Belgium, Gonnelle⁴ reported 17 cases of edema with serum albumin levels of 4.5 to 5.0 gm per 100 cc. Govaerts and Lequime⁵ studied the serum albumin concentration and osmotic pressure in several cases of this condition and found that the latter was reduced out of all proportion to the former, which was either normal or moderately reduced. Govaerts and Lequime admit that it is difficult to interpret these findings but suggest that reduced tissue osmotic pressure may contribute to edema formation in persons suffering from starvation. Such observations suggest that the Starling hypothesis may not entirely account for "hunger edema." It is apparent that further studies, especially those using new tools, such as the ultracentrifuge and electrophoresis, must be devised to determine the mechanism of edema formation in starvation.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

CONGENITAL DEFECTS DUE TO RUBELLA

The status of rubella as a completely benign childhood disease was abruptly altered in 1941, when Gregg reported some unusual findings from Australia Following an uncommonly large epidemic of rubella, numerous women were delivered of infants in whom various congenital defects were observed These defects included cataracts and other ocular malformations, deafness, heart defects and defects of the head and extremities Other investigations substantiated these early findings, but the magnitude of the problem has not yet been determined

At present, the Department of Public Health is undertaking a survey to determine whether or not rubella produces similar effects in Massachusetts and, if so, how extensive the problem is The year 1943, which is relatively recent and in which a total of nearly 35,000 cases of rubella were reported, was selected for study Questionnaires are being prepared to go to all physicians in the Commonwealth Descriptive pamphlets and questionnaires will subsequently be sent to each woman, seventeen to forty-nine years of age, reported as having rubella during 1943 The following data are desired the trimester of pregnancy in which the mother became ill, whether there was subsequently a miscarriage, premature delivery or full-term delivery, and whether the infant was normal or demonstrated any congenital defects Negative reports are as essential as positive reports, to establish a comparison

Although 1943 was primarily selected for study, the Department is interested in receiving any information pertaining to this problem, regardless of the date It is essential to establish not only the fact of the condition but also its incidence. Data from all interested physicians, hospitals, schools and other institutions will be welcome

† Four year average

COMMENT

Diseases reported at figures above the seven-year median included diphtheria, German measles, undulant fever, chicken pox and measles The last-named established a new record for this disease for the month, whereas chicken pox reached its second highest peak, the highest having been recorded in 1944

Among diseases reported below the seven-year median were bacillary dysentery, meningococcal meningitis, mumps, scarlet fever and whooping cough

Lobar pneumonia was again reported at a record low for the fourth successive month

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from Haverhill, 1, total, 1

Antbrax was reported from Boston, 1, total, 1

Diphtheria was reported from Boston, 2, Brockton, 5, Brookline, 1, Cambridge, 1, Chelsea, 2, Everett, 1, Gloucester, 1, Haverhill, 1, Lynn, 1, Medford, 1, Shirley, 1, Mills, 1, Taunton, 4, total, 22

Dysentery, bacillary, was reported from Grafton (State Hospital), 3, Tewksbury State Infirmary, 1, Milton, 1, total, 5

Hookworm was reported from Lynn, 1, total, 1

Malaria was reported from Abington, 1, Belmont, 1, Boston, 16, Brockton, 2, Brookline, 1, Cambridge, 3, Chelsea, 1, Clinton, 1, Gloucester, 1, Grafton, 1, Haverhill, 1, Hudson, 1, Lawrence, 1, Lowell, 1, Lynn, 1, Malden, 3, Medford, 3, Milton, 1, Newton, 1, Peabody, 1, Plymouth, 1, Quincy, 1, Revere, 2, Seekonk, 1, Somerville, 2, Southbridge, 1, Tann-ton, 1, Templeton, 1, Waltham Regional Hospital, 2, Water-town, 1, West Springfield, 3, Westwood, 2, Winchendon, 1, Winthrop, 1, Woburn, 4, Worcester, 2, total, 68

Meningitis, meningococcal, was reported from Boston, 1, Franklin, 1, Lowell, 2, Malden, 1, Marblehead, 1, Quincy, 1, Weymouth, 1, total, 8

Meningitis, Pfeiffer-bacillus, was reported from North Adams, 1, total, 1

Meningitis, pneumococcal, was reported from Cambridge, 2, Fitchburg, 1, Lynn, 1, total, 4

Meningitis, other forms, was reported from Boston, 1, Winthrop, 1, total, 2

Meningitis, undetermined, was reported from Chicopee, 1, Palmer, 1, Pittsfield, 1, Worcester, 1, total, 4

Salmonella infections were reported from Lawrence, 1, Peabody, 1, Salem, 1, total, 3

Septic sore throat was reported from Boston, 5, Haverhill, 2, Holbrook, 1, Medford, 1, Quincy, 1, Springfield, 1, Westford, 2, total, 13

Tetanus was reported from Chelsea, 1, West Springfield, 1, total, 2

Trichinosis was reported from Medford, 1, New Bedford, 1, total, 2
 Typhoid fever was reported from Springfield, 1, Worcester, 1, total, 2
 Undulant fever was reported from Adams, 1, Ashland, 1, Billerica, 1, Newton, 1, Quincy, 1, Southboro, 1, total, 6

MISCELLANY

Dr Harold J Jeghers, formerly associate professor of medicine at Boston University School of Medicine and a member of the staffs of the Boston City Hospital and Evans Memorial, Massachusetts Memorial Hospitals, has recently been appointed professor of medicine and director of the Georgetown University School of Medicine. He has also become physician-in-chief at the Georgetown University Hospital.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Essentials of Body Mechanics in Health and Disease By Joel E Goldthwait, M.D., LL.D., Lloyd T. Brown, M.D., Loring T. Swaim, M.D., and John G. Kuhns, M.D. With a chapter "The Heart and Circulation as Related to Body Mechanics" by William J. Kerr, M.D. Fourth edition. 12", cloth, 337 pp., with 128 illustrations. Philadelphia: J. B. Lippincott Company, 1945. \$5.00.

The first three editions of this authoritative manual were published under the title *Body Mechanics in Health and Disease*. The fourth edition has been carefully revised and partially rewritten. The chapter on disabilities of the feet has been entirely rewritten, and new chapters on geriatrics and on the heart and circulation have been added. The illustrations have been augmented, and an extensive bibliography is appended to the text. In this edition emphasis is placed on the maintenance of physical fitness and health and on the prevention of many deformities due to faulty body mechanics.

NOTICES

ANNOUNCEMENTS

Dr Edward A. Adams announces that after June 1, 1946, his practice will be limited to general surgery and consultation at 44 Oliver Street, Fitchburg.

Dr William Corwin announces the opening of an office for the practice of psychiatry and neurology at 95 State Street, Springfield.

Dr J. Edward Flynn announces his release from military service and the reopening of his office for the practice of surgery at 475 Commonwealth Avenue, Boston.

Dr Arthur J. Gorney announces his return to the practice of otolaryngology and related plastic surgery at 14 Charlesgate West, Boston.

Dr Patrick J. Mahoney is resuming practice at 96 Bay State Road, Boston.

Dr Jacob Mezer, having returned from military service, announces the opening of his office for the practice of gynecology and obstetrics at 171 Bay State Road, Boston.

Dr John P. Rattigan announces his return from service in the U. S. Naval Medical Corps and the opening of his office for the practice of internal medicine at 422 Beacon Street, Boston.

Dr Benjamin Tenney announces his return from military service to the practice of gynecology and obstetrics at 330 Dartmouth Street, Boston.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY

The annual meeting of the American Board of Obstetrics and Gynecology was held in Chicago, Illinois, from May 5 to May 11, 1946, at which time one hundred and forty-one candidates were certified.

A number of changes in Board regulations and requirements were put into effect. Among these is the requirement that case records must now be forwarded to the Secretary's Office from thirty to sixty days after the candidate has received notice of his eligibility for admission to the examinations for certification. At this meeting the Board also ruled that it will not accept the nine months' residency as an academic year toward years of training requirements following the termination of the official period of intern and residency acceleration, April 1, 1946.

The next written examination (Part I) for all candidates will be held in various cities of the United States and Canada on Friday, February 7, 1947, at 2:00 p.m. Candidates in military service are requested to keep the Secretary's Office closely informed of changes in address.

Applications are now being received for the 1947 examinations. The closing date for these applications will be November 1, 1946.

For further information and application blanks, address Dr. Paul Titus, Secretary, 1015 Highland Building, Pittsburgh, 6.

Number 2

GANGRENE OF THE HAND FOLLOWING TREATMENT FOR PRURITUS OF HEPATOTOXIC ORIGIN*

FRANCIS R. KENNEY, M.D.†

BOSTON

THE treatment of severe pruritus is often so difficult that one is prone to seize on any remedy that seems to offer relief. Many patients enter the hospital with badly excoriated skin, traumatized by their attempts to alleviate the itching, and suffering from lack of rest and sleep. In this report we wish to describe our experiences with a patient suffering from acute hepatitis and jaundice who was given ergotamine tartrate for control of itching and who subsequently developed serious constitutional symptoms and gangrene of one hand.

A 56-year-old, married woman entered the New England Baptist Hospital on January 28, 1945, with a chief complaint of jaundice. This had been present for 2 weeks and was associated with clay-colored stools, dark urine and marked pruritus. For 2 months previously, the patient had been more tired than usual, had lost 10 pounds in weight and had noticed increasing flatulence and belching, with occasional vomiting. Increasing dyspnea with exertion was also present. There had been no severe pain at any time, but there had been occasional mild twinges of discomfort in the right upper quadrant of the abdomen. The past history revealed tonsillectomy 17 years previously, subtotal thyroidectomy for adenomatous goiter 15 years previously and resection of a parathyroid tumor 10 years previously.

System review was negative except for moderate deafness, dyspnea after climbing one flight of stairs, soreness in the right upper quadrant of the abdomen and occasional belching, flatulence and vomiting. The menopause had begun 3½ years previously. The patient had had arthritis for several years.

Physical examination on admission showed a markedly icteric, moderately deaf woman lying restlessly in bed. There were excoriations of the skin of the abdomen and extremities, apparently caused by scratching. All the upper teeth and the lower molars were absent. Tonsillar tabs were present. There was an old thyroidectomy scar. The liver was palpable, both right and left lobes being enlarged, and there was a questionable, rather hard mass between the liver edge and the umbilicus. There were external hemorrhoidal tabs, slight pitting edema of the anterior tibia and marked dorsal kyphosis. Finally, there appeared to be slight arthritic changes of a rheumatoid nature in the fingers. The blood pressure was 140/70, the pulse 72, and the temperature 98.6°F.

The urine had a specific gravity of 1.010 and gave an acid reaction. It contained a slight trace of albumin and no sugar. The urobilinogen was demonstrable in a dilution of 1:8. The sediment contained 7 or 8 white cells per high-power field, a few bacteria and epithelial cells. It contained no bile.

The hemoglobin was 12.4 gm., and the red-cell count 3,580,000. The white-cell count was 6,650 with 68 per cent

neutrophils and 32 per cent lymphocytes. The prothrombin time was 81 per cent of normal. A blood Hinton test was negative. The nonprotein nitrogen was 34 mg. per 100 cc., the total serum protein 8.9 gm., with the albumin 5.3 gm. and the globulin 3.6 gm. The serum bilirubin was 21 mg. direct. The stool was brown.

The clinical impression on admission was carcinoma of the head of the pancreas or stones in the common duct, mild congestive failure and rheumatoid arthritis. On further inquiry, it became known that the patient had received injections of cinchophen for her arthritis during 2 weeks in November, 1944, in another town. In addition, she had received sodium salicylate, iodine, colchicine, streptococcal vaccine and an unidentified stomachic.

As the laboratory work became known and the patient was further observed, the clinical impression changed to that of subacute yellow atrophy based on a toxic hepatitis, in addition to a possible obstruction of the common duct.

The patient was placed on a high-protein, high-carbohydrate, low-fat diet, along with a parenteral preparation of vitamin K and calamine lotion with 1 per cent phenol for the pruritus.

On February 3, a partial gastrointestinal series showed no intrinsic lesion in the upper tract and no widening of the duodenal loop. Daily urine urobilinogen tests were positive in dilutions varying from 1:5 to 1:16. Because of anorexia, infusions of 5 per cent glucose in water fortified with 100 mg. of thiamin chloride were given daily. Two cubic centimeters of crude liver extract was given intramuscularly every 24 hours.

On February 7, because of continued uncontrollable itching, ergotamine tartrate (Gynergen) was started in doses of 1 mg. twice daily. This produced slight to moderate relief.

Amino acids were added to the daily infusions on February 12 and were continued for 6 days. The serum bilirubin rose to 26 mg. 10 days after admission, but since the stools remained brown, the diagnosis of obstruction of the common duct was abandoned. The prognosis appeared poor, even though the serum bilirubin had declined to 12 mg. by February 13. The patient was drowsy, lethargic, anorectic and still jaundiced. The pruritus was fairly well controlled by the ergotamine tartrate.

On February 14, after 16 mg. of ergotamine had been given, it was noted that both radial pulses were weak and that numbness had developed in the right hand. On February 15, the right radial pulse could not be obtained and the numbness persisted, accompanied by aching in the right arm.

On February 17, neither radial pulse was obtainable and there was severe pain in the right hand. On this date a mottled blue-gray color first appeared on the fingers of both hands. This was intermittent and associated with some coldness of the fingers. Pulsations were present in the popliteal, posterior tibial and dorsalis pedis arteries, the feet and toes were warm and there were no color changes in the lower extremities. Although the pain in the right hand persisted, the color changes were inconstant. Ergotamine tartrate was still being given, the total dosage having reached 26 mg. This was immediately discontinued. During the following 24 hours the extremities were unchanged, except that there was a constant dusky, pale-blue color in both hands, which were

*From the Service of Dr. Howard M. Clute and Dr. Thomas J. Anglem at the New England Baptist Hospital.

†Second assistant visiting surgeon, Massachusetts Memorial Hospitals.

cold. In addition, both brachial and axillary pulsations had disappeared.

On February 21 cervical sympathetic block was done, and shortly afterward the patient thought that a little feeling had returned to the fingers of the right hand. Papaverine hydrochloride was given subcutaneously, $\frac{1}{2}$ gr. every 3 hours. Buerger's exercises were started.

Although the right hand was warmer following the sympathetic block, the poor color persisted. Between February 17 and 22, the temperature gradually rose to 102°F. The left hand returned to a normal color within 36 to 48 hours following the cervical block and remained so, with only a sensation of numbness and slight stiffness in the fingers. In addition, the axillary, brachial and radial pulses returned to both arms within 48 hours after the sympathetic block and 72 hours after stopping the ergotamine tartrate.

The patient's general condition improved rapidly. By February 27 the temperature was normal and the anorexia

March 29 and the drug was stopped on April 3, when the patient experienced some anorexia and regurgitation of food, vomiting once. She was out of bed on the 2nd postoperative day and was discharged home on the 9th day, with the wound healing well. Penicillin was discontinued on the day before discharge.

A good cosmetic result was achieved, but it was expected that the function of the hand would be poor, although the stump of the thumb might prove useful. The last report from the patient stated that she was able to write with her right hand.

It seems logical that any pharmacologic depressant of the sympathetic nervous system might give therapeutic assistance in severe pruritus, since it is held by some that an increased irritability of the

FIGURE 1

was markedly diminished. The jaundice became less, and on March 12 the serum bilirubin was down to 2.5 mg. Papaverine was stopped on March 4.

Lines of demarcation began to form on the right hand, and it was evident that gangrene was present. By March 20, the lines between normal and gangrenous tissue were quite plain, and penicillin was started in doses of 100,000 units daily in preparation for operation. Within a few days the lines of demarcation were extremely sharp and the general appearance of all viable tissue was much improved (Fig. 1).

On March 27, the thumb and first finger of the right hand were amputated. During the operation several blood vessels were seen to be filled with old blue-black blood and the vessel walls themselves appeared to be in poor condition. The final pathological report, however, showed no evidence of specific vascular disease and only dry gangrene of the tissues.

Postoperatively the patient did satisfactorily. She was given $1\frac{1}{2}$ gr. of papaverine every 3 hours by mouth, with the thought that any slight dilatation of the vessels would assist healing. This dosage was reduced to $1\frac{1}{2}$ gr. every 6 hours on

sympathetic nerve endings is responsible for this condition. Following this line of reasoning, Lichtman¹ in 1931 reported 4 cases treated with ergotamine tartrate for pruritus, of renal origin in 2 cases and of hepatic origin in 2. All these patients were given 1 mg. three times a day by mouth. In each case an excellent result was obtained shortly after therapy was begun. The drug was stopped immediately on obtaining relief, and no recurrence of the pruritus was noted. Lichtman therefore recommends a dose of 1 mg. orally three times a day as a useful antipruritic in hepatic and renal disease. In addition, the drug is to be stopped as soon as relief is obtained.

In 1933, Snell and Keyes² reported a series of 12 cases in which ergotamine tartrate was used for relief of pruritus. They administered an oral dose of 1 mg three or four times a day or a subcutaneous or intramuscular dose of 0.5 to 1.0 mg daily. They concluded that the pharmacologic action of ergotamine tartrate was so little understood that it would be advisable to regard it as a purely empirical remedy. They reported no toxic effects in their cases, but considered this a possibility. The frequency with which pruritus occurs is brought out in this article, the authors mentioning that this complaint was noted in 60 per cent of patients with choledocholithiasis and in a slightly higher percentage of those with stricture of the common bile duct, especially those of long standing, and in cases in which there was extensive hepatic injury. In neoplastic obstruction itching was encountered in at least 75 per cent of cases.

In 1936, Yater and Cahill³ reported a case treated for severe pruritus by 0.5 mg of ergotamine tartrate three times a day by injection. This was given for six and a third days, the total dosage being 9.5 mg. On the second day coldness of the arms occurred as a premonitory symptom of toxicity, and as a final result it was necessary to amputate both legs halfway between the knee and the foot. No permanent injury to the upper extremities occurred. Microscopic examination showed that all the arteries were constricted to varying degrees and often thrombosed in the less constricted regions. The authors described the two forms of ergotism, the convulsive and gangrenous types.

In the same year, Gould, Price and Ginsburg⁴ described a case in which the patient was thought to be suffering from toxic liver damage, secondary to neoarsphenamine. Because of pruritus, 0.25 mg of ergotamine tartrate was given subcutaneously daily for four days. Following the second injection, pain and coldness developed in the extremities, soon followed by cyanosis and impaired sensation. Both hands also became cold and cyanotic, the dorsalis pedis and tibial arteries could not be felt and the pulsation in the popliteal artery was barely palpable. Ergotamine tartrate was discontinued and the patient was given vasodilators (glyceryl trinitrate and amyl nitrite), as well as strychnine sulfate. Progressive involvement of the legs occurred until there was blackness of the lower two thirds, complicated by skin macerations. There was definite narrowing of the fundal arteries. The patient became worse and died four days after the initial dose of ergotamine tartrate. Post-mortem examination showed all the arterioles examined to be contracted.

In 1939, Comfort and Erickson⁵ presented an excellent review of the untoward effects following the use of ergot and ergotamine tartrate. They also believed that there was no clear, rational explanation for the occasional marked relief noted in cases of pruritus following the use of ergotamine. A brief

review of the literature concerning untoward effects from the use of ergot and ergotamine tartrate was given. They divided this review into groups according to the condition for which ergotamine was given, these groups included puerperal sepsis, menorrhagia, hyperthyroidism, jaundice and pruritus. Following this review, Comfort and Erickson presented 2 cases treated at the Mayo Clinic with ergotamine tartrate in which untoward effects developed. In the first case the drug in oral doses of 1 mg three times a day was given for pruritus, apparently due to stricture of the common duct. A total of 23 mg was given. Following this there developed coldness of all extremities, cyanosis of the right hand and wrist and inability to move the fingers of the right hand. Pulsations could not be felt in the left ulnar or the right radial and ulnar arteries, and could be felt only slightly in the left radial artery. Continuous hot moist packs were applied, and ephedrine was given. In addition to this, alcohol was given by mouth every four hours. On this regime the extremities gradually improved. The final result in this case showed some residual muscular atrophy in the right hand. The second case was diagnosed as metastatic carcinoma of the liver. Pruritus was controlled by one to three tablets of ergotamine tartrate daily. Eight days following admission to the hospital, the radial pulse could be palpated only with the greatest difficulty, and ergotamine tartrate, of which 16 mg had been given, was discontinued. On the next day the pulses were more easily palpable, and the following day they had returned to their normal volume. These authors concluded that some of the untoward effects from the use of one of the preparations of ergot or ergotamine tartrate recorded in the literature have followed the administration of doses larger than those compatible with good practice. In other cases, however, the bad effects have apparently been dependent on the existence of an individual idiosyncrasy to the drug, since extremely small doses have occasionally produced toxic results. In spite of the many reported cases of ergotism, the authors concluded that the value of ergotamine tartrate in doses of proper size, provided adequate precautions are taken, was such that they would continue to use the medication, especially in the control of pruritus and migraine. They emphasized the contraindications to its use and the danger of the development of ergotism, and pointed out that the onset of this complication may be suspected early by frequent examination of the arterial pulsations and of the extremities for spasm and by recognition of its early symptoms. For treatment they recommended pilocarpine subcutaneously, magnesium sulfate parenterally and alcohol orally.

In 1938, von Storch⁶ thoroughly reviewed the literature concerning ill effects following the use of ergotamine tartrate. At that time it was said that the great majority of such effects occurred because

cold. In addition, both brachial and axillary pulsations had disappeared.

On February 21 cervical sympathetic block was done, and shortly afterward the patient thought that a little feeling had returned to the fingers of the right hand. Papaverine hydrochloride was given subcutaneously, $\frac{1}{2}$ gr every 3 hours. Buerger's exercises were started.

Although the right hand was warmer following the sympathetic block, the poor color persisted. Between February 17 and 22, the temperature gradually rose to 102°F. The left hand returned to a normal color within 36 to 48 hours following the cervical block and remained so, with only a sensation of numbness and slight stiffness in the fingers. In addition, the axillary, brachial and radial pulses returned to both arms within 48 hours after the sympathetic block and 72 hours after stopping the ergotamine tartrate.

The patient's general condition improved rapidly. By February 27 the temperature was normal and the anorexia

March 29 and the drug was stopped on April 3, when the patient experienced some anorexia and regurgitation of food, vomiting once. She was out of bed on the 2nd postoperative day and was discharged home on the 9th day, with the wound healing well. Penicillin was discontinued on the day before discharge.

A good cosmetic result was achieved, but it was expected that the function of the hand would be poor, although the stump of the thumb might prove useful. The last report from the patient stated that she was able to write with her right hand.

It seems logical that any pharmacologic depressant of the sympathetic nervous system might give therapeutic assistance in severe pruritus, since it is held by some that an increased irritability of the

THE DICK TEST IN MILITARY PERSONNEL*

With Special Reference to the Pathogenesis of the Skin Reaction

LOWELL A. RANTZ, M.D.,† PAUL J. BOISVERT, M.D.,‡ AND WESLEY W. SPINK, M.D.§

THE Dick skin test has been widely used for the detection of human beings susceptible to scarlet fever and has proved to be useful for this purpose. It has been demonstrated that a skin rash rarely appears in any but Dick-positive patients during an infection by a scarlatinogenic strain of hemolytic streptococcus. There is no evidence that failure to react to the erythrogenic toxin confers protection against infection by hemolytic streptococci. In fact, recent investigation shows that cases of respiratory infection associated with skin rash caused by these organisms occur much less frequently than do those without a rash, because a large number of highly invasive strains of streptococci are apparently unable to form the skin-reacting substance.

It has usually been believed that the reaction following the injection of culture filtrates of the hemolytic streptococcus in the Dick test is due to the direct toxic action of the products of the organism on the skin.¹ The inhibition of this reaction by the preinjection incubation of the toxin with immune serum, or in vivo in the insusceptible human

being, may then be regarded as an ordinary toxin-antitoxin neutralization. Others have suggested that the phenomenon is the result of hypersensitivity of the allergic type.²

The frequency of occurrence of positive Dick reactions has been repeatedly determined in relation to age³ and geographical distribution.⁴⁻¹⁰ Recently an opportunity arose to investigate the effect of certain geographical and environmental factors on the incidence of positive and negative Dick reactions in a large group of military personnel. The information obtained is presented because a similar group does not appear to have been previously studied in the United States, and because the results permit a reinterpretation of the pathogenesis of the Dick reaction.

METHODS

The skin test was performed exactly as described by the Dicks.¹ All needles and syringes were boiled in distilled water and rinsed with toxin before use. A skin-test dose of toxin (Lederle) contained in 0.1 cc of solution was injected intracutaneously in the flexor surface of the forearm. The test was read twenty to twenty-four hours later and was regarded as positive if the diameter of the area of erythema was greater than 1 cm.

A possible source of error has been introduced by the failure to perform control tests with heated toxin for the purpose of excluding so-called "pseudo-reactions." The Dicks and many others have con-

*This work was done during a field study by the Commission on Hemolytic Streptococcal Infections, Board for the Investigation and Control of Influenza and Other Epidemic Diseases in the Army Preventive Medicine Service, Office of the Surgeon General, United States Army. The Laboratories of the Department of Medicine, Stanford University School of Medicine, San Francisco, California, were made available to the commission for certain purposes.

†Assistant professor of medicine, Stanford University School of Medicine.

‡Assistant professor of pediatrics, Yale University School of Medicine.

§Associate professor of medicine, University of Minnesota School of Medicine.

of overdosage, pre-existing sepsis or obliterative vascular disease. No serious effects were reported in the author's experience in treating migraine headaches with this drug for the previous five years. He concluded that, although migraine headaches may apparently be treated with considerable success by the use of carefully controlled doses of ergotamine tartrate, its use in the treatment of pruritus is fraught with considerable hazard.

Several experimental studies have been reported in an attempt to clarify the pharmacologic and toxic effects following the administration of ergotamine tartrate. In 1935, McGrath⁷ reported on experimental ergotism produced in the tails of rats treated with ergotamine tartrate. The lesions were quite similar to that of thromboangitis obliterans, with marked cellular proliferation and swelling in the intima, most strikingly seen in the arterioles and small arteries. Administration of theelin protected the rats from pathologic changes, and McGrath concluded that the failure of thromboangitis obliterans to develop in the female was probably due to protection from estrogenic substances.

In 1938, however, Loewe and Lenke⁸ found that theelin and Progynon B were ineffective in preventing the development of gangrene in white rats, even when treatment was begun on the day that ergotamine was first given.

From the previously described cases and others,²⁻²⁵ it becomes apparent that a considerable number of cases of peripheral gangrene have occurred following the use of ergot or ergotamine tartrate preparations. The most important toxic disturbances due to ergotamine tartrate besides gangrene are headache, nausea, vomiting, diarrhea and dizziness. Less frequently observed are weakness, itching, coldness of the skin, thirst, drowsiness, cyanosis, collapse, anginal pain, tachycardia, or bradycardia, muscular twitching or cramps, convulsions, hepatic symptoms and sudden death.

Contraindications to the use of ergotamine tartrate are well summarized by von Storch⁶ as a septic state, cardiovascular disease and obliterative vascular disease. Treatment should be used with caution in cases of arteriosclerosis, hepatic or renal disease and hypersensitivity to the drug. It is certainly most strongly to be recommended that careful daily palpations of the radial and ulnar arteries, along with those of the posterior tibial, popliteal and dorsalis pedis arteries, be carried out in all cases in which ergotamine tartrate is being used for the control of pruritus. The patient should also be carefully questioned for any symptoms of numbness, tingling, coldness or pain in the extremities. Should any of these symptoms or signs be noted, the drug should immediately be stopped and measures taken to promote peripheral circulation. These measures include the intravenous use of papaverine hydrochloride and the oral use of ephedrine, papaverine hydrochloride and alcohol. Magnesium sulfate

intravenously or 1 per cent pilocarpine subcutaneously may be helpful. Roch²³ has suggested acetylcholine. In this condition, however, by far the most effective treatment is prophylaxis which consists of the immediate cessation of ergotamine tartrate therapy when any of the previously mentioned signs are noted. It cannot be too strongly stressed that most careful daily observation of the patient by the physician in charge is essential for the safe administration of this medicine. The physician who is driven to its use for the control of intractable pruritus should be well aware of its dangers and be prepared to take immediate steps to counteract them.

CONCLUSIONS

In treating severe pruritus one should be careful in the choice of a therapeutic agent, with regard to the possible toxic effects. The worse is the general systemic condition of the patient, the greater is the danger of toxicity from drugs used to control pruritus.

Ergotamine tartrate is definitely useful as an antipruritic agent provided one realizes the potentialities for severe reaction in its use.

If ergotamine tartrate is to be used as an antipruritic, the following precautions seem indicated. The dose should not exceed 1 mg three times a day orally. At least once daily, and preferably twice, the patient should be questioned and examined concerning pain, coldness, cyanosis, loss of arterial pulsations, impaired sensation and tingling in the extremities. Should any of these signs or symptoms develop, the drug should immediately be discontinued and appropriate therapy started.

Therapy for ergot poisoning following the use of ergotamine tartrate includes the following: papaverine hydrochloride (0.02-0.03 gm) intravenously or orally or both, ephedrine (24 mg) orally, alcohol (15 cc every four hours) orally, magnesium sulfate (15-20 cc of a 3 per cent solution intravenously), 1 per cent pilocarpine (1 cc subcutaneously), acetylcholine, and sympathetic block with novocain.

The use of ergotamine tartrate is contraindicated in the presence of a septic state, cardiovascular disease and obliterative vascular disease. It should be employed with great caution in cases of hepatic or renal disease, arteriosclerosis and hypersensitivity to the drug.

positive Dick reactions was extremely high (38.8 to 41.3 per cent) among those who had lived in New England, New York or the Far West, it was lower (20.0 to 33.3 per cent) among those from the remainder of the North, Middle West and West, and extremely low (8.7 to 14.0 per cent) in the border states, the Southeast and the Southwest. These differences are very great and of unquestionable statistical significance. As an added check, the duration of military service and age of men in the low-incidence areas were studied and discovered to approximate the distribution of these factors in the group as a whole.

DISCUSSION

Certain information obtained during this study is of general interest. Slightly more than 25 per cent of white American men of military age were Dick positive. The frequency was increased below and decreased above the age of twenty, but the differences were not great. These facts are in accord with previous investigations in the United States.

The incidence of positive Dick reactions was the same in men admitted to the hospital with virus-type respiratory disease as in those with Group A hemolytic streptococcus sore throat, demonstrating that there is no relation between the Dick reaction and immunity to infection by hemolytic streptococci. This fact has been previously established¹¹ but has been insufficiently emphasized.

It is also worth while to record the information that men become less frequently Dick positive with prolonged military service. This effect did not become manifest before the end of the twelfth month. As much as one year of service in the study post, which was located in an area of extremely high in-

Although this theory of the pathogenesis of the Dick reaction has been widely accepted, it is not in accord with most of the studies that have been made for the purpose of elucidating it. Most important is the established fact that infants are Dick negative regardless of the reaction of the mother or the presence or absence of antitoxin in her or in the infant's serum.¹²⁻¹⁴ Most of these babies later become Dick positive, but do so at irregular intervals. Children of various ages who have been tested over considerable intervals of time have been observed frequently to acquire but rarely to lose the ability to react to the erythrogenic toxin.^{15, 16} Maternal antitoxin transferred through the placenta should disappear promptly in children, and all subjects capable of becoming Dick positive should have done so by the end of the first year of life. More elaborate experiments have demonstrated that it is possible to transfer passively Dick positivity to Dick-negative subjects by the transfusion of serum.¹⁷ In addition, it has been pointed out that the streptococcal erythrogenic toxin is much more heat stable than the other well known bacterial toxins.

All these facts, and others not described, have been correlated in an interpretation that states that the ability to react to Dick toxin is not a natural characteristic of human beings but is acquired as the result of exposure to the hemolytic streptococcus, and that it is a hypersensitivity phenomenon of the allergic type.²

A comparison of the geographical incidence of positive Dick reactions and of hemolytic streptococcus sore throat might permit a decision which of the two mechanisms described above is correct. If the ability to react to Dick toxin is a natural characteristic that may be lost by exposure to hemolytic streptococci and the subsequent development of immunity following clinical and inapparent infection, the incidence of positive reactors should be low in areas where streptococcal disease occurs frequently and high in those in which this disease is

sidered this precaution to be unnecessary with suitably prepared testing materials. The observed positive reactions appeared to be of the correct type and were reversed during convalescence from scarlet fever in the expected manner.

RESULTS

The reaction to Dick toxin of 1280 white men suffering from acute respiratory disease admitted to a large station hospital was determined on the second hospital day. There was no discrimination, all cases during the study period being included. The test was positive in 27.8 per cent. Three hundred and ninety-seven of these men were believed, on clinical and bacteriologic grounds, to suffer from Group A hemolytic streptococcus sore throat. Twenty-four developed a typical scarlatinaform rash. A significant antistreptolysin or antifibrinolysin response or both was observed in 87.9 per cent of 342 of these patients in whom suitable tests were done, indicating that the clinical impression was usually correct. The Dick test was positive in 27.7 per cent of this group. The relation of the results of this test to the clinical course of hemolytic streptococcus respiratory disease will be presented elsewhere.

The disease was clinically compatible with a virus type of infection in 803 cases, and no Group A hemolytic streptococci were isolated from the nasopharynx. Of these men, 27.2 per cent were Dick positive. In another 80 patients the diagnosis was not clearly established on clinical and bacteriologic grounds. These infections appeared to be examples of virus-type respiratory disease occurring in persons who were nasopharyngeal carriers of Group A hemolytic streptococci. An antibody response was demonstrated in only 2 of 18 cases studied in this group. Thirty-five per cent of these patients were Dick positive.

Age

The relation of age to positive Dick reactions is presented in Table 1. Men over the age of twenty

TABLE 1 *Relation of Age to Dick Positivity*

21 to 24	397	92	23.1
25 to 30	290	64	22.1
31 to 35	128	35	27.3
36 and over	49	15	30.6

react to Dick toxin in less numbers than do younger men. The groups are large and the results are of statistical significance. A precise analysis was not made, but it is logical to assume that men in the older age groups frequently had had a more pro-

longed military service, which, as will be demonstrated, decreases the incidence of positive Dick reactions.

Duration of Military Service

When the study group was considered in relation to the duration of military service, it was discovered that the incidence of Dick positivity was high (34.3 per cent) in men who had been in the Army for less than a year and fell abruptly to much lower levels (22.0 per cent) among all those who had served for a longer period of time. No significant difference existed in the rate of six-month periods of service from thirteen to more than thirty-six months. The essential data are presented in Table 2.

Duration of Service in Study Post

This survey was conducted in an Army camp located in an area in which hemolytic streptococcus

PRIMITIVE MEDICINE*

M. F. ASHLEY MONTAGU, M.D.†

PHILADELPHIA

ANY discussion of so-called "primitive medicine" must begin with an essential clarification. When one speaks of primitive medicine, one refers to a special body of traditional knowledge which compared with that of the present appears crude and undeveloped. It is desirable to remember that this lack of development is a function not of the group's biologic status but of its cultural status, and that its cultural status is, again, a function not of its biologic makeup but primarily of the history of its experience as a social group.

The comparatively undeveloped medical knowledge and practice of isolated man is simply a reflection of the fact that such a person has not experienced the kind of culturalizing conditions that have fallen to the lot of man living in the Western world. The former has not developed so complex a culture as has Western man, for the reason that he has been completely isolated from the main stream and cross currents of cultural interchange and development to which man in the Western world has been exposed. Any reference to the medicine or culture of isolated man — a phrase in many ways to be preferred to the usual "primitive man" — in terms of inferiority to our superior selves is to be deprecated. To compare the cultural achievements of any two groups for the purpose of valuation, it is first necessary to determine whether they have had the same or similar opportunities for cultural achievement.

Compared with the history of experience and opportunity that Western man has enjoyed, that of isolated man has been of the most minimal kind. This fact should sufficiently account for the cultural differences that one observes, as a whole, to exist between them, and it should explain the

comparative lack of complexity that characterizes the medical knowledge of isolated man.

However ridiculous and stupid some of the medical beliefs and practices may appear to the sophisticated Westerner, it should be enough here to say that this attitude is but a confession of ignorance and a lack of a historical sense and something of human understanding, for the medical lore of isolated man represents a perfectly harmonious part of the acquired wisdom of the group and a thoroughly integrated part of the social structure as a whole. Occurring in the culture in which it does, it could hardly be other than it is.

The time has long since passed when the medical lore, the leechcraft, of isolated peoples could be classed with the quaint and queer in the album of medical curiosities. Nor is it sufficient to record the bare details of that lore, as is almost invariably done in present-day histories of medicine. Medicine is a social phenomenon, and the medicine of any people can only be effectively understood as such. For this reason it is necessary to gain an understanding of the society as a whole if its medical knowledge and practice are to be understood in their full significance — if, indeed, that knowledge and practice are to be understood at all. This is particularly the case in isolated societies, in which medicine is much more closely integrated with the institutions and beliefs of the society as a whole than it is in the highly diversified structures of Western societies. Failure to recognize these elementary facts makes the chapters on primitive medicine in contemporary histories of medicine their least satisfactory ones.

Special studies of the medicine of several primitive peoples that have been written by physicians with anthropologic training are now available, and there is a vast amount of material to be found in the field studies of anthropologists.¹⁻¹⁴ There is a serious need of additional special field studies of the medicine of particular primitive peoples, but until these have been carried out, a highly desirable step

rare. On the other hand, if a positive Dick reaction is the result of hypersensitivity acquired by exposure to the hemolytic streptococcus, the exact reverse should occur.

When the data on the geographical distribution of Dick positivity obtained during this study are considered, it is discovered that the latter situation prevails. It is difficult to state accurately the frequency of hemolytic streptococcus respiratory infection throughout the United States, but extensive studies of acute respiratory disease in military personnel and inspection of the distribution of cases of scarlet fever and rheumatic fever in the armed forces and in the civilian population indicate that the hemolytic streptococcus is rarely the cause of respiratory disease in the southern states¹⁸⁻²². Elsewhere this organism is known to be responsible for a large but unknown percentage of infections of the respiratory tract. It seems quite certain, therefore, that men whose premilitary residence has been in an area in which streptococcal disease occurs infrequently are rarely Dick positive.

An examination of published studies reveals that this fact has been previously established. A careful study in Rio de Janeiro^{6, 6} showed that scarlet fever was extremely infrequent and that Dick-positive persons were rare in all age groups. Many other investigations⁴⁻¹⁰ have confirmed the fact that positive Dick reactions are infrequent in the Tropics and in isolated Arctic communities where streptococcal disease is usually believed to be infrequent²³. The fact that these surveys were carried out in a variety of racial groups in areas in which the incidence of streptococcal disease had been poorly assessed detracts from their usefulness.

The frequency of positive Dick reactions in a large number of Chinese students from all sections of the country was determined by Lai.⁷ Those who had lived in northern China, where scarlet fever is widespread and severe, showed a frequency of positive reactions three times that of those whose residence had been in the tropical provinces, where the disease is rare.

It may be said to be established that the incidence of positive Dick reactions is low in the parts of the world in which infection by hemolytic streptococci is an infrequent occurrence. The possibility that this is due to racial variations is eliminated by the study of homogeneous population groups in China and in the United States.

Previous workers have believed that this phenomenon is to be explained on the basis of a high natural immunity to the streptococcus toxin, although at least one observer failed to find circulating antitoxin in the serum of Dick-negative persons in the Tropics.⁸

The present study strongly suggests that a hypothesis based on natural immunity is in error, since there appears to be no reason to suppose that white residents of the southern United States should have

natural antibodies differing from those present in persons living in the North.

Since Dick positivity and hemolytic streptococcus infection occur infrequently in certain areas, and the reverse is true, the inescapable conclusion is that contact with the streptococcus is essential for the establishment of skin reactivity to the erythrogenic toxin. If this is the case, it is impossible to regard this material as a true toxin, and the skin reaction must be regarded as a hypersensitivity phenomenon. It is recognized that this skin reaction is somewhat different from others of an allergic nature, since it may be readily reversed during convalescence from scarlet fever or by active immunization. That this may be due to desensitization rather than to true toxin-antitoxin neutralization has been suggested.²

If the conclusion is acceptable that exposure to streptococcal infection is necessary for the establishment of a positive Dick reaction, the frequency of positive reactors in a population may be used as a rough guide to the incidence of streptococcal infection in the group. The occurrence of nonscarlatigenic strains of Group A streptococci suggests an important source of error in such a procedure, since many examples of streptococcal disease occur in certain populations as the result of infection by such streptococci but sensitization of the affected persons may not result.

SUMMARY

The reaction to Dick toxin of 1280 white men of military age was studied.

The frequency of positive reactions was least in men over the age of twenty and in those who had had more than twelve months of military service.

Positive Dick reactions were infrequent in men whose premilitary residence had been in a geographical area in which the incidence of hemolytic streptococcus disease is known to be low.

It is concluded that exposure to the hemolytic streptococcus is essential for the establishment of a positive Dick reaction.

The Dick reaction is probably the result of acquired hypersensitivity to the products of the streptococcus rather than of a natural susceptibility to a true toxin.

We are indebted to Miss Elizabeth Randall, who performed all the skin tests, and to Mrs. Helen Rantz, who compiled the data.

drugs as quinine, curare, opium and digitalis, to name but a few, were all discovered by isolated peoples as specifics for certain conditions, and that in such practical phases of medicine as surgery many serious operations have, from earliest times, been performed on human beings with complete success. Fractures of every sort have been repaired, dislocations corrected, and obstructions removed.

This paper will attempt a brief inquiry into the types of disease concepts that are to be found in the cultures of isolated peoples, and their classification, so that they may be efficiently compared and articulated with those of the technologically more advanced Western world.

As a basis for comparing the medical concepts and practices of isolated peoples with those prevailing among the peoples of Western societies, three causes may be recognized that are universally known to explain disease. The first is natural cause, the second is human agency, and the third is supernatural agency. If the disease can be explained in terms of material agencies, it is attributed to natural causes, but if it is attributable to the action of some human being who has, for example, resorted to sorcery, the malady is assigned to a human agency. Finally, if the illness is held to be due to some spiritual or supernatural being or principle it is ascribed to the direct action of the supernatural.

The three possible causes of disease here stated are those that, among sophisticated and isolated peoples alike, are accepted the world over. The principal difference between the concepts held by peoples with widely differing cultures is that groups with greater educational advantages—in the Western sense of those words—tend to place more confidence in the natural causation of disease, whereas isolated peoples tend to place more confidence in its supernatural causes. As everyone is aware, even in our own society there are really very few persons who do not retain some belief in the supernatural causation of disease, nor is it necessary to point out that the less educated a person is, the likelier he is to place his faith in the supernatural explanation of disease. In many parts of Europe there exist at the present time populations who believe quite as much in the supernatural causation of disease as do the most isolated peoples.*

When a man can come more or less closely to discerning the empirical elements in a situation, his reasoning is likely to be logical and based on common sense. On the other hand, when the situation with which he is concerned defies such definition, he tends to accept explanations that are no more explicitly denotable than are the conditions with which he is dealing ‡

*For an admirable study of the folk medicine of a European peasantry—of the Balkans in this instance—see Kempf¹⁶ and Brendle and Unger¹⁷.

†Any object to which the human organism can react serially point for point may be referred to as 'explicitly denotable'. The objects known as 'finger' or 'penny' or 'stone' belong to this class. Such entities as 'Fascism', 'democracy' and 'nation' to which a person cannot react in this way are denoted by terms referable to 'implicit language usage'.¹⁷

In most isolated societies it is a firm tenet of belief that the world is animated by some spiritual principle or power. This, in fact, is the definition of the supernatural—namely, the belief in the unseen, mysterious and wonderful spiritual force or powers that pervade the universe. The supernatural is generally personified in the form of a being or several beings, each with particular powers that greatly transcend anything of which man alone is capable. This belief is called "animism" by anthropologists. The power of the supernatural may also manifest itself in a disembodied form, as a supernatural quality or an attribute of objects, just as color, weight and hardness are attributes of objects. Examples are the "orenda" of the Iroquois, the Algonquian "manitou" and the Melanesian "mana". This form of the belief in the power of the supernatural is known as animatism ‡.

In passing it may be noted that primitive religion may be regarded as the technic and result of supernaturalism. Religion differs from magic in that it makes no attempt to coerce but is directed toward entering into closer personal relations with the supernatural, one prays, beseeches or worships, but one never controls §.

In animistic societies it is, of course, a simple matter to explain almost everything of unknown causation as due to the activity of good or evil spirits. Magic consists of compelling these spirits to do one's bidding. Their manipulation for evil purposes is sometimes called "black magic," whereas their manipulation for good purposes is called "white magic." The practice of magic in any form is called "sorcery."

At the very outset one sees how intimately related to the character of a culture are the concepts of disease that it holds, for it is obvious that in a sophisticated society in which the experimental method occupies a prominent place, the doctrine of natural causes will be the one most generally accepted as an explanation of disease. Where the habit of thought associated with the experimental method is wanting and spiritistic beliefs are the dominant ones, the tendency will be to explain disease in terms of the supernatural.

CLASSIFICATION OF DISEASE CONCEPTS

Given the cultural character of a typical isolated society, there may be recognized seven main types of primitive disease concepts. These are as follows: sorcery or magic, breach of taboo, disease-object intrusion, spirit intrusion, soul or body loss, dreaming and independent occurrence.

‡There is serious question whether the distinction between animism and animatism can be legitimately maintained since in the final analysis the supernatural attributes of an object may be traced back to some definitely recognized personified spiritual agency. For an excellent discussion of this matter see Karsten¹⁸.

§In the discussion of these matters it is well to remember that there are no attitudes toward supernatural relations that are not taken toward human relations. Honor and awe are not given to human beings to the extent to which they are shown toward the supernatural beings: the gods. The only difference is one of extent.

would be a stocktaking of what is already known and an attempt at an analysis and systematization of this at present widely scattered knowledge. The attempt would be an extremely rewarding undertaking, and it is one that merits the attention of the serious student.

At this point I should like to discuss briefly the time-honored and perennial error that seems to have established itself in the minds of many writers on the subject — namely, the idea that both medicine and science grew out of magic. Magic may be defined as the process of manipulating the supernatural, of coercing or procuring it to do one's bidding by the performance of certain ritual acts. Science may be defined as verifiable and communicable knowledge, based on observation, experiment and reflection — in short, on doing one's utmost with one's mind, as Percy Bridgman has so fittingly put it. Now, magic and science both deal with causation, — magic with supernatural causation and science with natural causation, — and the reliance that people put on these two ways of manipulating the world in which they live is well-nigh universal. Both magic and science are mechanical procedures, but whereas the purpose of the former is the compulsion of the supernatural according to letter-perfect traditional rules of thumb, the latter has no place whatever for the supernatural, which is the main concern of magic. Science deals with cause-and-effect sequences in the natural world — experimentally gauged and determined. Magical cause and effect represent nothing but fabrications of the human mind operating in an imaginary world — the supernatural. Magic is based on a series of false analogies, whereas science is based on a rigorous testing and verification of repeatable experiences.

Every people defines the natural and the supernatural in its own way, but there is general agreement on the essential principles involved. It is only in certain sophisticated areas of Western society that some men have definitely discarded the picture of the universe as operating on two parallel and contrasted sets of causation. Primitive peoples recognize ordinary natural sequences of cause and effect, just as they also recognize more wonderful causations, — the supernatural, — technics that are not checked against natural laws but are solely concerned with manipulating a special potency that has its own rules apart from the matter-of-fact ones of craft and industry.

To manipulate the natural world man everywhere develops a material technology. No living or extinct people of whom there is any knowledge is ignorant of technologic facts. The very process of getting a living, even at the simplest imaginable levels, demands the development of certain technologic processes for manipulating the environment. The material culture of isolated peoples everywhere abundantly testifies to their ingenuity, inventiveness and technologic proficiency.

It should be fairly clear that where material technology is present, — and it is present in all human societies, — it becomes quite unnecessary to derive science from anything other than the development and practice of the technics involved and the reflecting and philosophizing on them in which man everywhere is wont to indulge.* A simple diagram will illustrate the actual relations. To manipulate the natural world man develops a material technology, and it is out of this that science eventually grows. To manipulate the supernatural

Natural World Technology	Supernatural Magic
Science	

world he develops a series of magical technics. There is no necessary association between the one and the other.

Close study of the conditions actually prevailing in isolated societies reveals the fact that magical and scientific activities are frequently pursued as parallel activities quite independently of each other. For example, to restrict the discussion to the medical referent, when a limb is broken it is set in accordance with the best available empirical knowledge that the native doctor as a highly specialized member of the tribe has been able to obtain. No magic or ritual is involved in the treatment of the injured limb. When a person has suffered from severe and prolonged headache his skull may be trephined, and if he does not get better it is trephined until he does — or dies. No magic is involved in this either. In short, isolated peoples have their rational medicine, which is based entirely on experience and into which no element of the magical enters. Experience has taught them that certain plants possess specific qualities of medicinal value, they are therefore rationally used, and so it is with many other facts and practices that have been acquired and developed through experience. Isolated peoples also have their magical medicine, in which the principal reliance is placed on the compulsion of the supernatural. All this is not to say that magical medicine and rational medicine or science are always unrelated, for the fact is that they are frequently related, and it is often quite difficult to disentangle them. This is, however, to say that persons who are members of isolated societies are by no means fools, and that they do not live under the unrelieved domination of a host of magical ideas and practices. Nor are they, as some writers have suggested, characterized by a prelogical type of thought. If anything they suffer from an excess of logic rather than from a deficiency of it. It is an interesting fact that such

*For primitive man as a philosopher see Paul Radin in *On the strictly scientific accomplishments of isolated peoples*. Professor Wilson Wallis of the University of Minnesota has gathered together a vast amount of material. This work is about to be published.

internal organs, the thin walls of which when they do not receive an adequate supply of oxygen become more and more permeable to the fluid part of the blood. Plasma escapes into the perivascular spaces, with a resulting high concentration of red corpuscles, and the victim dies of shock scarcely distinguishable from true wound shock.

To return to taboo, Webster ²⁰ writes

The authority of a taboo is unmatched by that of any other prohibition. There is no reflection on it, no reasoning about it, no discussion of it. A taboo amounts simply to an imperative thou-shalt-not in the presence of the danger apprehended. That any breach of the prohibition was unintentional or well intentioned matters nothing, no allowance is made for either the ignorance or the praiseworthy purpose of the taboo-breaker.

When sickness is believed to be produced by the breach of some taboo, expiation of the offence may sometimes be made with the assistance of a medicine man, who, by the performance of certain magical acts, may succeed in releasing the victim from the effects of his transgression.

Disease-Object Intrusion

In isolated societies it is a widespread belief that many types of illness are caused by the entrance into the body of some foreign object. Such morbid objects may find their way into the body either by direct human agency or by the action of some nonhuman agent. The disease object is usually regarded as carrying a spiritual essence, which is the real cause of the illness. Under such conditions it becomes the function of the medicine man to extract this object from the victim's body. The disease object may take almost any form, but it is always extremely small—a pebble, a splinter of wood or bone, a hair, an insect, a lizard or a worm. Removal of the object is usually accompanied by sucking on some part of the body, and in a short time the medicine man produces the pathogenic object from his mouth. This has, of course, been secreted there by him for production at the appropriate time, in much the same manner as many a modern physician, called on to deal with a patient who mistakenly believes that a fishbone has lodged in his throat, produces a fishbone that was never there. In either case the patient leaves perfectly happy in the knowledge that he will be troubled no longer. Since in many cases the illness was originally produced by suggestion, the sight of the object believed to have been the immediate cause of the disease is sufficient to work a cure.

Spirit Intrusion

When it is believed that disease is due to the presence in the body of some immaterial agent, such as a spirit, a ghost or a demon, one may speak of disease by spirit intrusion. This must be carefully distinguished from spirit possession, the latter resting on the belief that a person has been entered by a supernatural being, who then speaks through his host.

Such a person is not regarded as ill in the ordinary sense of the word. His insanity is, on the contrary, regarded as evidence that he has been honored by a supernatural being who has taken abode within the affected person's body. He is therefore respected as a holy one and is often consulted as an oracle.

There are three methods ordinarily used to eject the intrusive spirit from the victim's body—exorcism, mechanical extraction and transference. In exorcism, the evil spirit is ejected by conjuration. The spirit is removed by manipulative, surgical or similar means in mechanical extraction. Transference refers to the transfer of the disease object from the victim's body to some object. Exorcism is nearly always practiced together with one or both of the other methods.

Soul or Body Loss

Abstraction of the soul or a part of it or some part of the body is still another mode in which disease is believed to be produced. Among the Australian aborigines the abstraction of the kidney fat, or perhaps more correctly the fat of the greater omentum, is held to be a common cause of disease. It may be removed by sorcery as a punishment for the infringement, knowingly or unknowingly committed, of some rule, thus bringing about the death of the victim ²¹. Still more widespread is the belief in soul abstraction as the cause of disease and often of death. The soul may be abstracted by ghosts or sorcerers, or during sleep the soul may leave the body—as it is frequently believed to do in dreams—and meet with some accident on its nocturnal wanderings that prevents its return. The task of the medicine man is to discover the whereabouts of the missing soul by divination or other means and return it into the body of his patient.

Dreaming

Dreams may be the cause of sickness. In the Pacific and in the southwestern areas of North America, one may dream that one has eaten poisoned foods or that an animal has entered one's body, and wake up or fall ill shortly afterward. Furthermore, the dreamer may not himself suffer from the dream, but a relative of his may be afflicted.

Independent Occurrence

Minor ailments, such as leg sores, cuts, scratches and a host of other minor conditions, are regarded as arising independently of any action on the part of human beings or of higher powers. It is when a disease appears to threaten life that people begin to think of human or spiritual agencies. Attracting little attention, minor ailments do not afford material for speculation. When Rivers²² inquired of the Eddystone islanders of Melanesia what caused these minor ailments, they replied that they came of themselves and were not, therefore, the occasion

Sorcery or Magic

When it is believed that disease is produced by the activities of persons skilled in magic or by the manipulations of older persons who exercise some control over the supernatural, the disease is said to be produced by sorcery or magic. In isolated societies there are generally available a number of magical ritual formulas that can be enacted by anyone to compel the supernatural to produce disease and even death in some other person, whether of one's own or another tribe. In addition there is always present a special class of persons, the medicine men, who are particularly skillful in manipulating the supernatural for good or evil. These may be hired at almost any time to bring affliction to one's enemies.

The magic by which these conditions are produced is of two kinds, homeopathic or imitative magic and contagious magic. Homeopathic magic assumes that things that resemble each other are the same. An image, for example, is made of one's enemy and this is injured or destroyed, in the belief that the victim will thereby be injured or destroyed.

Contagious magic makes the assumption that things that have once been in contact are always in contact, therefore, whatever is done to the one must similarly affect the other. According to this view, a person is never really dissociated from any part of his body or anything that has been in contact with it. Thus, his nail parings, hair, spittle and clothing are all part of him, so that anyone who obtains possession of these can, at any distance, work his will on the person of whom they were once a part.

In practice both homeopathic and contagious magic are often combined, more exactly, whereas homeopathic magic may be practiced by itself, contagious magic will generally be found to involve an application of the homeopathic principle. Both branches of magic are comprehended under the general name of "sympathetic magic," since both assume that things act on each other at a distance through a connecting invisible ether.

Under such conditions of belief, causation of disease by sorcery is brought in to explain not only illnesses that have no obvious antecedent cause but also those in which the natural cause is obvious. For example, when a man stumbles and bruises himself or falls from a tree and injures himself, the cause is not ascribed to the boulder that was in the way or the rotten branch that broke or to some failure of co-ordination on the part of the victim. Instead, the accident, as one may loosely call it, is attributed to the act of a sorcerer.

Among the Australian aborigines, for instance, as among many other isolated peoples, death is never regarded as due to natural causes but is always ascribed to sorcery. With the assistance of a medicine man, the person responsible for causing

the death is then usually discovered and subsequently becomes marked for death.

Since the magical practices of the sorcerer are, to a large extent, part and parcel of the religious system of groups, it will be readily understood that religion and primitive medicine are closely associated with one another — an association that in civilized societies has been attenuated but never quite dissolved. With few exceptions, the diagnosis, treatment and prognosis of disease are all made by the medicine man, and when he is able to discover the cause, as he usually is, he can generally neutralize the effects of the maleficent spirits by some countermagic. When the disease object is capable of being abstracted directly from the victim's body, such abstraction is a simple matter for an expert medicine man. It is only in certain cases of breach of taboo that he, or anyone else, can do nothing.

Breach of Taboo

Taboo (originally a Polynesian word) may be defined as a prohibition the infringement of which automatically brings about its own punishment. Certain things are regarded as in themselves so dangerous that to break the taboo in connection with them results automatically in punishment without the mediation of supernatural or human forces. The occult power residing in a mystically dangerous object is transmissible and is therefore capable of affecting whatever comes into contact with it. The contact that most frequently automatically releases the occult punishing power is bodily contact. In many parts of Africa it is forbidden to touch anything from which the king or chief has eaten, be it the food or the plate from which it was taken. Anyone who willingly or unwittingly breaks this taboo is inescapably doomed to die, usually within a few days to a few weeks. So powerful is the force of suggestion here that the native who has broken the taboo often wastes away from no apparent cause.

The phenomenon of what has been called "voodoo death" is so interesting that a few words in explanation of the mechanism may be offered here. The evidence strongly suggests that death in such cases is due to the action of the sympathico-adrenal system in producing a marked decrease in blood pressure similar to that seen in wound shock. The blood volume is reduced until it becomes insufficient for the maintenance of an adequate circulation. Cannon¹⁹ writes

Thereupon deterioration occurs in the heart, and also in the nerve centers which hold the blood in moderate contraction. A vicious circle is thus established, the low blood pressure damages the very organs which are necessary for the maintenance of an adequate circulation, and as they are damaged they are less and less able to keep the blood circulating to an effective degree.

Constriction of the arterioles produces a dangerous fall in the oxygen supply of the capillaries of the

quence of the spiritistic beliefs that such peoples hold. Their ideas of causation may be wrong from our standpoint, or they may contain a grain of truth here and there, but given certain spiritistic concepts, the body of medical practice follows with a degree of consistency that we can only hope some day to equal. In short, it should be clear that, in his view of the nature of disease and its treatment, isolated man is no illogical unreasoning creature. He is, in fact, a thinker who, with the data at his disposal, does at least as well as we should do under similar circumstances. Let us, then, look on him with the respect and understanding that are his due.

CLINICAL NOTE

URETERAL CATHETERIZATION

C A HAYSMER, M D *

STONEHAM, MASSACHUSETTS

FROM a discussion that was recently heard it is evident that a simple technic for catheterizing the ureters in the presence of a vesicovaginal fistula is not well known. I therefore call attention

to a method that was successfully used a number of years ago. Since the fistula was of moderately large size, it would have been impossible to distend the bladder enough for successful ureteral catheterization with the usual technic. The problem was solved by soldering a nasal atomizer tip over a flexible eustachian catheter, allowing the catheter to project slightly beyond the atomizer tip. The arrangement is seen in the accompanying illustration (Fig 1). No doubt the cannula used in the Rubin test would have served equally well.

The tip of the eustachian catheter was inserted

FIGURE 1

to a method that was successfully used a number of years ago.

It was desired to catheterize the ureters for their better identification during the closure of a high

through the vagina and fistula into the bladder. The atomizer tip thus occluded the fistula. The fluid passing through the eustachian catheter quickly dilated the bladder, allowing easy catheterization of the ureters.

*Surgeon, New England Sanatorium and Hospital

of rites such as naturally follow disease ascribed to the neglect of religious injunctions

Such minor ailments do not, therefore, necessarily fall into the domain of what would be called natural causation. Since they are unimportant, no one thinks enough of them to attribute them to any cause, and since they do not require any appeal to magical or spiritual agencies for cure, they are treated with domestic remedies

PRIMITIVE MEDICAL PRACTICE

A brief account of some of the more practical devices to which isolated man resorts in various parts of the world will serve to convey some idea of his ingenuity and the closeness of many of his practices to modern ones, or even their identity with them

Among the Ashanti of West Africa, inoculation for smallpox or against snakebite is successfully undertaken. In smallpox, the contents of a pustule are rubbed into an incision made in the skin. In the treatment for snakebite, the procedure is almost identical with the most recently devised methods. Veins are punctured by the use of splinters of stone or bone or by the use of a little arrow, which is shot into the vein from a miniature bow. Cupping and bloodletting are widely practiced, cupping is usually carried out by powerful suction with the mouth through a bone tube or similar instrument. Drainage from wounds is sometimes secured by means of sections of bamboo. Foreign bodies are extracted and abscesses opened with a thorn or a sharp-pointed instrument.

Suture or tight bandaging to promote union is not unknown among some tribes. Stitching of small wounds is carried out by means of thorns. A highly original method of suturing a wound is practiced among certain Indian tribes of Brazil. Both edges of the wound are allowed to be seized and brought together by the sharp head-nippers of certain ants, whose bodies are then rapidly cut off, one ant after another is used until the wound is closed.

Ulcers are frequently treated by cauterization with hot ashes or with heated blades and irons. In the treatment of fractured bones, splints and occasionally casts made of clay are used. On the whole, the results obtained by the native bonesetters are said to be extremely good. Trephining of the skull has already been mentioned. At all times a serious operation, this is skillfully performed by the native surgeon with a blade of stone or glass. There are skulls in museum collections that show that persons have been operated on in this manner as many as four or even five times. Evidence of healing around the bone edges shows that there has been good recovery in these cases.

Medicines are given in the form of decoctions, poultices, embrocations, salves and infusions of various sorts. Hydrotherapy, dietetics and massage

are widely practiced. Enemas are administered by means of primitive appliances, and fumigations, inhalations, snuffs, nasal douching and instillations are also more or less widely practiced. This list of medical practices could be widely extended, but enough has been said, it is hoped, to indicate that the medical resourcefulness of isolated man is scarcely less than our own.

A few words may be added concerning the medicine man. How does a person become a medicine man? The pattern varies with different peoples. In some tribes the position is hereditary, in others the addiction to epileptiform states is the best qualification, or a man may come to be recognized as possessing a special gift for setting broken bones. In still other tribes the would-be medicine man must undergo a special course of training, and in certain societies there are even distinct grades of medicine men—for example, among the central Australian aborigines. Here the three grades of medicine men are those who are made by the spirits, those who are made by a special class of mischievous spirits and those who are initiated by other medicine men. The first two grades are more highly regarded than is the third. In each case the man himself believes that he is especially capable of becoming a medicine man. Women may become medicine women in the same manner. Practically everywhere women are the midwives and child doctors. Among the American Indians one may become a medicine man in a variety of different ways. Among the central Algonquin peoples, for example, there still exists a secret society known as the Midewiwin. This society is the repository of most of the medical knowledge of the tribe—a sort of college of physicians—into which one may gain entry by apprenticeship in early youth or by payment of the necessary fees and acquisition of the proper knowledge at any later time. It is a great honor to be a graduate of the Midewiwin. Different degrees of medicine men are recognized, according to the type of initiation they have undergone, and there are different types of specialists in the various disorders to which man is heir.

In many other cultures a person becomes qualified to treat a disease by virtue of the fact that he himself has recovered from that disease. In Africa a man may become a doctor by apprenticing himself, for several years and at an appreciable fee, to an already established medicine man, who then teaches him what he should know. A graduate medicine man may go in for postgraduate work by purchasing still higher secrets from others whose practice has brought them great renown.

* * *

From this presentation of the concepts of disease held by isolated peoples it will be seen that their medicine represents a perfectly rational system. Their medical practices are a most logical conse-

coming seen in true idiopathic cardiospasm. Furthermore, the filling defect seen under the fluoroscope is not a true picture of the extent of the growth. The lesion may appear to be inoperable or questionably inoperable, yet actually be a relatively small carcinoma with extensive spasm.

Meyer and Kozoll⁵⁵ in an editorial on gastrostomy reviewed the records of 80 patients on whom gastrostomies were performed between 1941 and 1944. Forty-three patients died within two months of the performance of the gastrostomy. As these authors point out, such results speak for the futility of gastrostomy, even as a preliminary procedure, in resection of the esophagus.

I believe that most patients with carcinoma of the esophagus do not need a gastrostomy, either as a preliminary or a palliative procedure. A few of these cases can be determined to be inoperable by inspection of the liver with the peritoneoscope, and others are found to be inoperable at the time of exploratory thoracotomy. In those that are operable the problem of gastrostomy does not arise because the stomach is mobilized and anastomosed directly to the end of the esophagus. In those that are inoperable the patient's nutrition can in many cases be fairly well maintained by bougienage, with a previously swallowed thread used as a guide. Such patients are also given x-ray treatment.

In cases of carcinoma of the esophagus and in those of carcinoma of the stomach invading the cardia, Sweet⁵⁶ believes that direct inspection of the growth through the esophagoscope assists in making a correct diagnosis. A biopsy should always be obtained at such an examination and usually confirms the existence of carcinoma. The extent of the growth in the deep layers of the esophageal wall, however, cannot be determined by this method. Roentgen-ray visualization is of greater value for this purpose and gives more accurate information. Because of the frequency of direct invasion of the left main bronchus by the tumor in cases of carcinoma of the midesophagus, it is imperative to perform a bronchoscopy in all such cases. In this way an unnecessary exploration of the tumor through the chest may be avoided.

Benign Stricture

Clark and Adams⁵⁷ have reported 5 cases of trans-thoracic esophagogastrostomy for benign stricture of the lower esophagus. There were no deaths. In selected cases, trans-thoracic esophagogastrostomy offers the patient complete relief of symptoms without the necessity of repeated dilatations or the unpleasantness of a gastrostomy. None of the 5 patients were considered to have cardiospasm. In 1 case the stricture followed the ingestion of lye, in another it was associated with generalized scleroderma, and in 3 cases no etiologic factor could be ascertained.

Cardiospasm

Field⁵⁸ compares the effects of amyl nitrite, glyceryl trinitrate and octyl nitrite on achalasia of the cardia in 5 children. He reports that octyl nitrite relaxed the cardia and produced clinical improvement in 4 cases. The fifth patient failed to respond and on further investigation was found to be suffering from congenital stricture of the lower end of the esophagus. Field states that octyl nitrite is superior to amyl nitrite because its odor is pleasanter and less pungent than that of amyl nitrite, because it is less volatile and can thus be administered in an inhaler, which is a much more convenient form, and because clinically it produces relief and stops vomiting, whereas amyl nitrite often produces nausea and vomiting. The advantages of octyl nitrite over glyceryl trinitrate tablets or liquor glyceryl trinitrate are as follows: it is quicker in action, allowing less chance for food to be vomited, the necessary relief can easily be regulated by inhalations, according to the esophageal sensations felt by the patient, and clinically it produces relief and stops vomiting, whereas the vomiting continues under treatment with the other nitrites. The Octrite Inhaler* is a glass tube, with a vulcanite cap at each end, containing cellulose pellets impregnated with octyl nitrite. During use, both caps are removed and the inhaler is applied to one nostril, the other being closed. The author states: "The child now approaches his meals with the certainty that he can take them. No longer is he in fear that a heavy discomfort in the chest will bring eating to a stop, for he knows that this can be relieved without fuss by a sniff from the inhaler." The life of the inhaler tube varies from seven to twenty-eight days. The author further states that octyl nitrite inhalation also produced favorable results in adults suffering from cardiac achalasia.

Clagett, Moersch and Fischer⁵⁹ point out that the vast majority of patients who have cardiospasm obtain excellent results from dilatation of the cardia by means of the hydrostatic dilator, and that it is only in the exceptional case that surgical intervention becomes necessary. Approximately 70 per cent of these patients are completely relieved by one course of treatment. In 30 per cent of cases there is a tendency for the condition to recur. The recurrence may take place at any time from immediately after treatment to twenty-five years after it. If the condition does recur, the great majority of patients can be successfully relieved by subsequent dilatation. Dilatation of the esophagus by means of the hydrostatic dilator can be employed with little risk, in these authors' experience the risk having been less than 0.1 per cent. In 2 to 5 per cent of cases hydrostatic dilatation does not prove efficacious and surgical intervention is indicated. Of the surgical procedures that have been recom-

ESOPHAGOSCOPY

Benign Tumor

Adams and Hoover⁴⁵ report 3 cases of benign tumor of the esophagus and include a review of the literature. Many of these tumors were incidental discoveries at autopsy. The number of cases discovered and recorded during the last eleven years owing to good x-ray technic and esophagoscopy is over half as large as the number of cases recorded in the preceding two hundred and twenty years. In a pathological classification of these tumors there were 35 polyps, 10 myomas, 9 papillomas, 8 fibromas, 6 cysts and 5 or less each lipomas, adenomas and unclassified tumors. There were 1 aberrant thyroid gland, 1 benign giant-cell tumor, 1 hemangioma, 1 lipomyoma, 1 neurofibroma and 1 osteochondroma. In 2 of the cases reported by the authors the tumors were removed by open operation, the third was removed with the aid of a suspension laryngoscope after the tumor had been drawn into the oral cavity by means of an esophageal speculum.

Harper and Tiscenko⁴⁶ have discussed benign tumor of the esophagus and its differential diagnosis. Benign tumors are relatively rare as compared with malignant tumors. The case reported is that of a benign intrinsic extramucosal tumor of the esophagus in which the diagnosis was made roentgenologically by exclusion.

Carcinoma

Borges⁴⁵ analyzed 153 cases of cancer of the esophagus. Ninety-nine cases received esophagoscopic examination, and positive biopsies were obtained in 83. Distant metastasis was not the rule, the lymph nodes in the posterior mediastinum and those about the left gastric artery were the most frequently involved. The author believes in radical resection whenever possible.

Tomlinson and Wilson⁴⁶ have studied esophageal carcinoma in British West Indian and Panamanian Negroes. Although recent reports state that this tumor is far more frequent in white males, especially in those of Jewish extraction, than in West Indian and Panamanian Negroes, the authors found 50 cases in Negroes, Indians and mestizos. In 50 cases studied at autopsy, the periesophageal lymph nodes were grossly invaded in every case. In British West

Indian Negroes, carcinoma of the esophagus ranked third among all the types of carcinoma observed at autopsy.

Boros⁴⁷ states that carcinoma of the esophagus is one of the most frequent of all malignant diseases and is oftenest found in the male sex (75 per cent). Although his report, from the New York City Cancer Hospital, is extremely discouraging, the author mentions a glimmer of encouragement in the realm of radical surgery, referring in this connection to the work of Churchill and Sweet,⁴⁸ Wookey,⁴⁹ Garlock⁵⁰ and Ochsner and DeBakey.⁵¹

In an analysis of 599 cases of cancer, Toreson⁵² found 19 cases of secondary involvement of the esophagus, an incidence of 3.2 per cent, 14 of the tumors originating in the breast, 2 in the pancreas, and 1 each in the testes and mediastinal lymph nodes, in 1 case the origin was undetermined. In 12 cases sufficient esophageal obstruction occurred to cause clinical symptoms. From this analysis, it is evident that secondary carcinoma of the esophagus is not infrequent and that dysphagia occurs in about half the cases.

An unusual case of multiple carcinomas was reported by Holland⁵³ in a fifty-five-year-old woman. In 1933 she had an adenocarcinoma of the right breast removed, in 1939 a squamous-cell carcinoma of the esophagus and a small basal-cell carcinoma of the left cheek were treated by x-ray, and in 1942 an adenocarcinoma of the colon (Grade 2) was removed. Incidentally, in 1943, she developed a mild diabetes and had a cholecystectomy for cholelithiasis. At the time of the report, twenty-eight months after removal of the fourth carcinoma, the patient was without physical or roentgen-ray evidence of any malignant disease. The author states that this is one of the first recorded cases of carcinoma of the esophagus with a five-year cure following irradiation therapy.

In an article on the surgical treatment of some lesions of the lower esophagus and upper stomach, Bradshaw and O'Neill⁵⁴ call attention to the fact that it has been stated that a positive biopsy must be secured before the operation is undertaken and, of course, is highly desirable in all types of surgery. On the other hand, small lesions in certain localities at the cardia are not readily accessible to the esophagoscope, gastroscope or fluoroscope. A valuable aid in such cases is the occurrence of spasm of the lower esophagus, which does not present the smooth

Case Records of the Massachusetts General Hospital In discussing this case Castleman,⁶⁵ the pathologist, stated his belief that the entire difficulty was related to the use of the gavage tube before the patient entered the hospital. The patient was the first of twins born seven weeks prematurely. The birth weight was 3 pounds, 1 ounce. The other twin weighed 2 pounds. Both children vomited frequently, and the other child died after one week. The patient was fed human milk by gavage many times while in the hospital. In the clinical discussion Farber⁶⁶ noted that gavage feeding of premature babies is frequently a necessity and saves many lives. It may be the cause of ulceration of the esophagus, however, particularly when the feedings are performed by inexperienced people. Such ulceration may form the starting point for infection, which may end in bacteremia. Pathologically, it was believed that the pulmonary lesions were almost certainly due to aspiration of the vomitus, which must have been mostly milk. It is also possible that at times some of the food fed by the gavage tube slipped down the larynx.

Rankin⁶⁶ reports a perforated ulcer of the esophagus following a burn. In 1842, Curling first described as a clinical entity an ulcer of the duodenum following a burn. To this day the etiology remains unknown.

The most popular theories for ulcer following burn are those of action of a burn toxin, stasis due to blood concentration, stasis due to low blood volume and adrenal activity, the embolic theory, the septic theory, the hypothalamus theory, the autonomic theory and the theory of nutritional disturbance. These ulcers are extremely rare, occur most frequently in children, perhaps reflect a severe toxemia, are seldom recognized during life and in general are an enigma in the medical literature. A case of perforated so-called "Curling's ulcer" of the esophagus with hemorrhage is reported. This occurred in a boy aged four years who had received second-degree burns to his thighs, buttocks and abdomen two days before admission to a hospital and died a few hours after it. Although none of these cases have been treated surgically, the only hope for the patient lies in immediate operation.

Smithers⁶⁷ has made a study of short esophagus (thoracic stomach) and its association with peptic ulceration and cancer. He first gives a historical sketch of congenital short esophagus and then discusses the theories regarding the association of thoracic stomach with peptic ulceration of the esophagus. Finding objections to the theories of congenital short esophagus and of fibrosis and constriction, he puts forward his own theory as follows:

Congenitally short oesophagus is rare, being seldom found at autopsy. Many cases so diagnosed during life have an acquired or an apparent shortening, rarely demonstrable after death, and resulting from hiatus insufficiency, sometimes developmental, more often acquired in later life. With the cardiac sphincter in the

thorax, released from any diaphragmatic control, gastric juice tends to flow into the oesophagus predisposing to peptic ulceration. Irritation of the oesophageal mucosa by gastric juice (or probably by oesophagitis from any cause) may produce irregular spasmodic contraction of the lower end of the oesophagus, which frequently appears, not only as irregular constrictions from side to side, but as longitudinal contraction or shortening. Relaxation of contraction and equalisation of pressure in the thorax and abdomen returns the herniated portion of the stomach to the abdomen by the time that a post-mortem examination is performed in cases where the oesophagus is of normal length. Heterotopic gastric mucosa may secrete gastric juice into the oesophagus or the gastric contents may reach it in other ways (for example, as the result of vomiting, rumination, or relaxation of the cardia following operations) in patients without a lax hiatus. Peptic ulceration of the oesophagus may occur in these patients without radiological evidence of shortening of the oesophagus. This theory (hiatus insufficiency, congenital or acquired, first, spasmodic shortening of oesophagus and ulcer, second) accounts for the known facts and overcomes the chief difficulties associated with the "congenital short oesophagus" and "fibrosis and contraction" theories. A new explanation of the shortening of the oesophagus, so real to the radiologist and often apparent at oesophagoscopy, but so little known to the pathologist, seemed to be required. An upward spasmodic contraction of the longitudinal fibres of the oesophagus during life, with relaxation after death, has been implied as a possible explanation in the theory put forward above. It seems possible that irritation which will produce oesophagitis or peptic ulceration of the oesophagus and irregular contraction of its lower portion may result in sufficient spasmodic contraction of the longitudinal fibres to produce apparent shortening and to retain a portion of the stomach in the thorax during life.

The article also deals with the association of achalasia and short esophagus and hiatus hernia and cancer, as well as short esophagus and cancer. Smithers states that the association of cancer and short esophagus may be purely fortuitous and that more case reports must be awaited before one can do more than speculate on the possible influence of achalasia and peptic ulcer associated with thoracic stomach.

Esophageal Varices

Patterson and Rouse⁶⁸ have treated 12 patients with esophageal varices by the injection of sclerosing solutions. They believe that such varices serve no useful purpose that cannot be served by other and nonvulnerable anastomoses between the portal and systemic venous circulations. In their experience, obliteration of these veins results in no appreciable unfavorable effects, instead, clinical improvement occurs soon after prevention of blood loss from a ruptured varix. Eight cases are reported in detail.

Whipple⁶⁹ in a discussion on portal hypertension calls attention to the fact that attempts to ligate the tributaries feeding into the veins of the cardia and esophageal varices have been extremely disappointing. Nor have the injection and coagulation methods to obliterate the esophageal varices been any better. At best, these procedures shut off one of the chief collaterals between the portal and systemic circuits and increase the portal hypertension. Using a vitallium tube, Whipple and

mended, the authors prefer esophagogastrostomy performed through a transabdominal approach. A review of the literature and the authors' results indicate that this is a safe procedure that accomplishes good results. Although good functional results are obtained, one should not expect retrogression in size of the dilated esophagus after the operation.

I believe that the value of surgical procedures for cardiospasm is still unproved. Sometimes the results are not satisfactory, especially when operation is undertaken without an adequate trial of dilatation with the mercury bougie or with the hydrostatic dilator in experienced hands.

Scott⁶⁰ has analyzed 85 cases of idiopathic dilatation of the esophagus—usually diagnosed as achalasia of the cardia or as cardiospasm. Aided by the information obtained from the use of spinal anesthesia as a tool of investigation, he believes that it is possible to recognize four different clinical types, which probably also differ from each other in their etiology. These types are achalasia of the esophagus, true cardiospasm, dilatation associated with a constriction at or just above the cardia and dolichoesophagus. In conclusion, Scott states that achalasia is probably the most frequent type. It usually responds well to dilatation. In true cardiospasm the reflex originating focus should be discovered and removed. Those cases caused by a partial constricting band near the cardia are few in number but are probably resistant to conservative treatment. Dolichoesophagus—an S-shaped lengthening with pooling of esophageal contents at different levels—should probably be operated on immediately on recognition. This type is extremely difficult to control when the dilatation becomes gigantic and is complicated by infection of the esophageal wall. Subdiaphragmatic esophagogastrostomy—of the Finney pyloroplasty type—appears to be the operation of choice in those cases of idiopathic dilatation of the esophagus that are resistant to the usual conservative measures. The symptomatic results of this operation are usually excellent, whether or not the dilatation of the esophagus is entirely corrected. The danger of the operation is not excessive when proper precautions are taken. After it has been employed more extensively, the number of cases in which it is indicated will probably be considerably increased, but it should never replace conservative dilatation in the majority of cases.

Weens⁶¹ calls attention to the frequent association of pulmonary disease with megaesophagus. In 3 cases the respiratory symptoms had completely overshadowed the digestive disturbances so that the presence of the megaesophagus was almost missed. It is this author's opinion that the pulmonary complications in megaesophagus are the result of aspiration into the bronchial tree of food

particles regurgitated from the esophagus into the pharynx, as is so often noted in this condition.

Hawes and Soule⁶² have reported 2 cases of severe cardiospasm associated with extensive pulmonary changes. One patient, a man aged fifty-seven, showed an interstitial fibrosis with cough and hemoptysis, the other, a man of thirty-one, manifested an increased density in the right upper lobe. The authors mention that patients with cardiospasm are often bothered with coughing and occasionally sudden paroxysms of strangulation, which are frequently precipitated by lying down. In the recumbent position the large reservoir of food and fluid may spill into the pharynx and be aspirated, and the patient may be aroused from his sleep by severe coughing. At times, the fluid entering the bronchi leads to pulmonary disease. Five types of pulmonary changes associated with cardiospasm have been observed roentgenologically—basal pneumonitis, lung abscess, bronchiectasis, pleural effusion and interstitial pulmonary fibrosis. In each of the 2 cases reported there was a long-standing asymptomatic pulmonary lesion, probably an interstitial fibrosis following aspirating pneumonitis.

Bird-Acosta⁶³ also calls attention to pulmonary suppuration as a result of esophageal overflow. Esophageal retention may be caused by carcinoma of the esophagus, strictures, foreign bodies, pulsion diverticulum, extrinsic esophageal pressure from adjacent tumors and cardiospasm. Of all the causes of pulmonary suppuration following esophageal overflow, cardiospasm, although a fairly common clinical entity, is rarely considered. The author reports 3 cases of pulmonary suppuration as a result of cardiospasm.

Cardioesophageal Relaxation

A case of cardioesophageal relaxation is presented by Berk.⁶⁴ It was diagnosed by roentgen ray examination and confirmed by esophagoscopy. Cardioesophageal relaxation, or insufficiency of the cardia, is an abnormality of unknown etiology in which gastric contents regurgitate passively into the esophagus through a patulous cardiac sphincter. It may be looked on as the direct antithesis of achalasia (cardiospasm). In this case careful x-ray studies were carried out in which it was concluded that there was no herniation of the stomach but simply a relaxation of the cardioesophageal junction. Esophagoscopy disclosed the esophagus to be dilated and flabby. No true hiatus hernia was seen, and no gastric mucosa. The impression of the esophagoscopist was insufficiency of the cardiac sphincter. The chief symptoms of this disease are epigastric distress and a lumpy sensation at the lower sternum.

Ulcer

The case of a thirteen-week-old male infant with traumatic esophageal ulcer has been reported in the

Case Records of the Massachusetts General Hospital In discussing this case Castleman,⁶⁵ the pathologist, stated his belief that the entire difficulty was related to the use of the gavage tube before the patient entered the hospital. The patient was the first of twins born seven weeks prematurely. The birth weight was 3 pounds, 1 ounce. The other twin weighed 2 pounds. Both children vomited frequently, and the other child died after one week. The patient was fed human milk by gavage many times while in the hospital. In the clinical discussion Farber⁶⁶ noted that gavage feeding of premature babies is frequently a necessity and saves many lives. It may be the cause of ulceration of the esophagus, however, particularly when the feedings are performed by inexperienced people. Such ulceration may form the starting point for infection, which may end in bacteremia. Pathologically, it was believed that the pulmonary lesions were almost certainly due to aspiration of the vomitus, which must have been mostly milk. It is also possible that at times some of the food fed by the gavage tube slipped down the larynx.

Rankin⁶⁶ reports a perforated ulcer of the esophagus following a burn. In 1842, Curling first described as a clinical entity an ulcer of the duodenum following a burn. To this day the etiology remains unknown.

The most popular theories for ulcer following burn are those of action of a burn toxin, stasis due to blood concentration, stasis due to low blood volume and adrenal activity, the embolic theory, the septic theory, the hypothalamus theory, the autonomic theory and the theory of nutritional disturbance. These ulcers are extremely rare, occur most frequently in children, perhaps reflect a severe toxemia, are seldom recognized during life and in general are an enigma in the medical literature. The article also deals with the association of achalasia and short esophagus and hiatus hernia and cancer, as well as short esophagus and cancer. Smithers states that the association of cancer and short esophagus may be purely fortuitous and that more case reports must be awaited before one can do more than speculate on the possible influence of achalasia and peptic ulcer associated with thoracic stomach.

Esophageal Varices

Patterson and Rouse⁶⁸ have treated 12 patients with esophageal varices by the injection of sclerosing solutions. They believe that such varices serve no useful purpose that cannot be served by other and nonvulnerable anastomoses between the portal and systemic venous circulations. In their experience, obliteration of these veins results in no appreciable unfavorable effects, instead, clinical improvement occurs soon after prevention of blood loss from a ruptured varix. Eight cases are reported in detail.

Whipple⁶⁹ in a discussion on portal hypertension calls attention to the fact that attempts to ligate the tributaries feeding into the veins of the cardia and esophageal varices have been extremely disappointing. Nor have the injection and coagulation methods to obliterate the esophageal varices been any better. At best, these procedures shut off one of the chief collaterals between the portal and systemic circuits and increase the portal hypertension. Using a vitallium tube, Whipple and

Blakemore have carried out vein anastomoses in 10 cases, half consisting of uniting the splenic vein and the left renal vein after removing the spleen and left kidney. In 5 other patients they have anastomosed the portal vein to the inferior vena cava. Whipple states that these procedures are as yet purely experimental. He quotes Blalock⁷⁰ as having performed splenorenal vein anastomoses for portal hypertension in 4 cases, in 2 of which there was a disappearance of ascites and remarkable improvement. On the other hand, Blalock's enthusiasm is somewhat curbed because the other 2 patients have died since operation from recurrent bleeding from esophageal varices.

In a description of the technic of using vitallium tubes in establishing portacaval shunts, Blakemore and Lord⁷¹ state in conclusion

Every one of the 10 cases of portacaval shunts went through a successful postoperative convalescence. The interval following operation has been too short in some to judge the results. However, in 6 of the 10 cases the improvement has already been so outstanding as to justify continuing the procedure. The Eck fistula operation is better tolerated by the patient, probably because of less blood loss during the procedure.

Lye Stricture

For esophageal poisoning due to lye Crowe⁷² believes in the Bokay prophylactic therapy, using a No. 10 Fr. eyeless catheter filled with lead or mercury and tied off at the open end. It should be wet with water or a lubricating jelly, gently passed down the esophagus and left in place for five minutes daily, starting on the third day after the patient has swallowed the lye. The size of the catheter should be increased until difficulty is encountered in passing it.

Pellagra

Fisher⁷³ discusses the findings in 17 patients ill with pellagra, all of whom had a characteristic glossitis. Marked dysphagia was frequent. Esophagoscopy revealed an intensive hyperemia and in some cases edematous mucosa. Multiple tiny ulcerations of the esophageal mucosa were noted in 9 cases. Barium studies of the esophagus in 8 cases showed many small, constricted areas along its course. Following the daily administration of 150 mg. of nicotinamide, 15 mg. of thiamin chloride and 15 mg. of riboflavin, the patients could swallow solid food without experiencing dysphagia in from three weeks to two months. There was progressive improvement in the objective findings and clinical symptoms.

Foreign Body

Richardson⁷⁴ reports 17 cases of esophageal obstruction due to impacted meat. Twelve of the patients had no teeth of their own, and several of the others had very poor teeth. Six patients had a normal esophagus, but the other 11 had a narrowing

or constriction of some portion. Spontaneous recovery can occur but is rare. Esophagoscopy may not be necessary if caroid or papain is used in a 5 per cent solution to dissolve the impacted meat.

Fistula

Abbott,⁷⁵ in an article on abnormal esophageal communications and their types, diagnosis and therapy, concludes that abnormal fistulous communications may occur from the esophagus into the bronchial tree, pleural cavity, mediastinum, pericardium and more remote tissue spaces. An esophageal fistula presents a serious hazard to the patient's life but not necessarily a hopeless one. This report adds 6 permanent closures to the 15 previously recorded. A review of the literature and a description of 23 additional cases is given. Two unusual cases of esophagopericardial fistulas are included in these reports. Another case, in which a fistula between the esophagus and the trachea occurred in association with Hodgkin's disease, is described, and this communication was successfully treated. To Abbott's knowledge, no previous similar cases have been reported. The symptomatology and diagnostic methods are described. The management of an esophageal fistula demands acute interest in methods of the patient's nutrition and the employment of early adequate drainage. Some fistulas close spontaneously under this regimen alone. Direct surgical attack on esophageal fistulas is applicable in some cases but can sometimes be obviated by endoscopic topical applications.

Abbott has reviewed 22 cases of abnormal esophageal communication that have been handled at the Barnes Hospital. The predominating cause was found to be malignant lesions of the esophagus or larynx. These constituted 13 of the 22 cases reported, and another case occurred in association with Hodgkin's disease. Two fistulas were secondary to chronic empyema, 2 were secondary to operative procedures, and 2 were associated with syphilitic aortic aneurysms. One patient developed a fistula following instrumentation, and another developed one in association with a congenital diverticulum of the esophagus, instrumentation having been used in this patient. No examples of fistulas in relation to tuberculous empyema or tuberculous mediastinal lymphadenitis are contained in this report. This is due, at least in part, to the fact that patients with chronic tuberculosis are usually relegated to sanatoriums. The diagnostic measure of the greatest value consists of x-ray visualization of the fistula, preferably with iodized oil to prevent barium irritation of the lung parenchyma. Considerable difficulty may be encountered in trying to visualize these communications directly with the aid of the esophagoscope, but the instillation of methylene blue within the esophageal lumen followed by bronchoscopic examination can be a helpful measure.

Moersch and Tinnev⁷⁶ have found that the most frequent site of acquired fistula between the esophagus and the trachea or bronchi is at or just above the bifurcation of the trachea. The left main bronchus is involved oftener than the right. Carcinoma of the esophagus was found to be the most frequent cause of this type of fistula, accounting for 36 per cent of 39 cases. Rarer causes were trauma, syphilis, tuberculosis and esophageal diverticulum, with a number of causes responsible for single cases. The etiology was unknown, however, in several cases. The clinical findings were found to depend on the primary pathologic changes and the size and location of the sinus tract. In esophageal cancer, the development of the fistula is suggested when, after a period of dysphagia, the ingestion of food is followed by cough, expectoration and dyspnea. This occurs particularly after taking liquids. X-ray study after the ingestion of iodized oil usually demonstrates the lesion. Because of the nature of the underlying disease, the prognosis is usually poor, and the cancer itself or pneumonia or mediastinal or lung abscess causes death. Small fistulas due to trauma may, however, last for years. In these cases surgical repair may be of value.

Haight⁷⁷ has presented the anatomic and surgical problems concerned with the correction of congenital atresia of the esophagus with tracheoesophageal fistula. Reconstruction of esophageal continuity by a single-stage operation consisting of an extrapleural closure of the tracheoesophageal fistula and an anastomosis of the esophageal segments offers the most satisfactory approach to the correction of the anomaly. A primary anastomosis of the upper and lower esophageal segments was done in 16 of the 24 patients on whom an exploration was undertaken. Six of the 16 patients for whom an anastomosis was performed were living seven months to three years and one month after operation, and the reconstructed esophagus was patent in all cases.

GASTROSCOPY

Complications

Fletcher and Jones⁷⁸ report on the risks of gastroscopy with the flexible gastroscope, having had 2 fatalities in twenty-eight hundred gastroscopic examinations. In both cases the Herman Taylor gastroscope was used. This gastroscope has a longer rigid and shorter flexible portion than the Wolf-Schindler flexible gastroscope. Both these fatalities were believed to be due to an error in judgment. In the first case, gastroscopy was probably contraindicated, since the patient's tissues might have been expected to be in a fragile state as a result of recent scurvy. In the second case, extra pressure was exerted when the tip of the gastroscope was lying in the hypopharynx, such pressure should not have been applied. In addition to their own cases, Fletcher and Jones have heard of 5 other fatal cases.

The Herman Taylor gastroscope was used in 5 of these 7 fatal cases. The authors call attention to the fact that gastroscopy with the flexible gastroscope is proving to be an indispensable means of diagnosis in diseases of the stomach and is rapidly becoming a routine procedure in almost every large hospital in the country. It is inevitable that many gastroscopies should be performed by inexperienced gastroscopists. They believe that beginners have a false sense of security in their use of the instrument, based on the rarity of reported accidents. It is important that all users of the flexible gastroscope should realize that there is a slight but definite risk associated with the passage of the instrument, and that in this, as in all endoscopic methods, the greatest circumspection is needed. These authors believe the main risk is that of perforation of the upper part of the esophagus and the hypopharynx. Both their deaths occurred in elderly women. They admit that the flexible part of the Herman Taylor gastroscope is 2 mm wider and is appreciably stiffer than the corresponding part of the Wolf-Schindler apparatus and that extra care may be necessary for its passage into the esophagus. On the other hand, they believe that the Herman Taylor model gives a better view of the stomach than can be obtained with the Wolf-Schindler instrument, and they consider it the gastroscope of choice provided it is passed with care.

Schindler⁷⁹ reports a case in which an apparent rupture of the stomach occurred during gastroscopy and pneumoperitoneum developed. At operation three hours later no trace of a lesion was found, although the pneumoperitoneum was present. The patient recovered.

Gastroscopic Study

According to Renshaw,⁸⁰ the diagnostic study of many patients cannot be considered adequate and complete without gastroscopy, which is an office procedure. Contraindications for examination are chiefly diseases of the esophagus and mediastinum. The limitations of gastroscopy are few, the main one being the so-called "blind areas" of the stomach, which vary in size. The procedure is indicated in further study of patients with negative roentgenologic findings in whom gastric disease is suspected, for classification of many cases with indeterminate, suspicious or inconclusive roentgenologic findings and for elucidation of certain obscure conditions, such as unexplained gross hemorrhage and gastrointestinal allergy. Gastroscopy in combination with roentgenoscopy and study of gastric content removed by the fractional method of gastric analysis has made the diagnosis of organic disease of the stomach comparatively simple.

Hardt, Hufford and Raben⁸¹ have made an analytical survey of patients examined gastroscopically and roentgenologically. One or more gastroscopic and roentgenologic examinations were performed

in 1132 patients who complained of symptoms suggesting the presence of gastroduodenal disease. The facts provided by the two methods were compared. The evidence conclusively demonstrates that gastroscopy should be performed before a definite diagnosis of normality can be made, since these authors' experience indicated that the gastroscope is the most efficient diagnostic aid in making a negative gastric diagnosis and in diagnosing all types of gastritis. In their experience, gastroscopy was superior to roentgenography in the diagnosis of all types of gastric ulcer, including marginal ulcers. The gastroscopist was correct in 89 per cent of all types of benign ulcerating lesions, and the roentgenologist correct in 58 per cent. The final stages of healing of the ulcer can be followed only by means of the gastroscope. Gastroscopy likewise is more accurate than roentgenography in localizing the ulcer and can detect earlier any changes suggesting malignancy. Some type of chronic gastritis was diagnosed gastroscopically in 19 per cent of 239 patients with duodenal ulcer, and gastroscopy thus added an important secondary diagnosis otherwise unobtainable. Gastric carcinoma was recognized gastroscopically in 94 per cent of the patients and by roentgenograms in 79 per cent, with a combination of both methods the lesion was detected in 98 per cent. Incomplete diagnosis gastroscopically occurred in 5 per cent, and the diagnosis had to rest entirely on the x-ray findings. On the basis of the authors' experience, gastroscopy is indicated in all cases of persistent or recurrent gastric complaints with negative roentgenologic findings in which the clinician still suspects the presence of gastric disease, in many cases of proved gastric ulcer in which operation is not performed but in which the lesion should be watched from time to time not only roentgenologically but gastroscopically, in cases in which the x-ray findings indicate a suspicious gastric lesion or in which a definite diagnosis cannot be made roentgenologically, and in all gastric carcinomas except those located at the cardia or well advanced in their course.

In 2 patients with negative gastrointestinal x-ray examination and negative gastroscopy, Hufford and Stonehouse³² took roentgenograms of the Cameron-Schindler flexible gastroscope in the esophagus passing through the cardia and in various positions in the stomach. The degree of flexion of the gastroscope was greatest in the esophagus, and was of a lesser degree in the fundus of the stomach just below the cardia. The flexible rubber tip of the gastroscope flexes acutely to the left and slightly forward as it passes through the hiatus esophagus into the cardia. The blind spots in the gastric wall are the parts that are in contact with or short of the focusing distance from the objective or inclined away at such an oblique angle that only a darkened area can be seen. The action of this gastroscope as recorded by the roentgenograms is shown to be

sufficiently flexible to pass through the normal anatomical channels without any undue stress or strain. The air inflated into the stomach during gastroscopic examination casts an identifiable shadow on the roentgenograms and unless eructated flows freely from the stomach through the pylorus, which shows satisfactorily the antral end of the stomach with peristaltic waves and a fairly good duodenal bulb. This report is well illustrated by eight roentgenograms.

From the beginning of World War II until December, 1943, Tanner³³ performed twenty-two hundred gastroscopic examinations on 1738 patients. In his clinic, the main use of gastroscopy was for diagnosis and observation of gastric ulcer. Of 631 cases of gastric ulcer, 159 were diagnosed solely by gastroscopy, since they apparently yielded normal x-ray findings. There are several reasons for the difficulty in diagnosis of many of the gastric ulcers by x-ray. For example, an acute ulcer may be too shallow to retain barium, or after a hemorrhage its base may be filled with blood clot, which prevents the entry of barium to the crater, or there may have been considerable delay after hemorrhage in x-ray examination of the patients, during which time the ulcer heals and the scarring may be missed roentgenologically. Thirty-nine of the patients with duodenal ulcer in this series also had a gastric ulcer, and cancer was also seen in 2 cases on which duodenal ulcer alone was suspected roentgenologically. Tanner agrees that even direct visualization of an excised ulcer of the stomach may not abide the truth as to its innocence or malignancy. Nevertheless, he writes, one is rarely in doubt after gastroscopic visualization, because vitality appears to accentuate the differences, and where such doubt exists a second inspection after ten days of medical treatment usually gives the clue. Certainly it is well worth while to examine gastroscopically every patient with an ulcer that is not healing rapidly under medical management. Superficial types of cancer may be missed roentgenologically. In this series there were 13 cases of cancer that had been considered benign or had not even been diagnosed roentgenologically.

Gastritis

Cutler and Walther³⁴ have reported on the significance of chronic gastritis in an Army general hospital, stating that a wide difference of opinion still exists on the clinical significance of the gastroscopic findings of chronic gastritis. They studied 333 soldiers. In conclusion they state

The gastroscopic surveys of asymptomatic subjects in this study and those by other workers have indicated that gastric mucosal changes can occur in symptom-free individuals. Notwithstanding, chronic gastritis is much more prevalent in the group of patients who do complain of chronic upper abdominal distress. In our series of such cases the incidence of chronic gastritis compares closely with the estimates of other workers previously cited. The frequent association of gastritis with duodenal

ulcer has again been corroborated in this study. The routinely uneventful response of these patients to an ulcer regimen does not militate against the symptomatic significance of chronic gastritis for the ulcer syndrome may be mimicked rather closely by patients who have chronic gastritis alone. Apart from the hypertrophic group simulating peptic ulcer a large group of patients with chronic gastritis show no uniform symptom complex. Because of the frequency of associated complaints unrelated to the patient's gastrointestinal system it is difficult to believe that a chronic gastritis can alone play the leading etiologic role. A sampling of consecutive cases of chronic gastritis has demonstrated the predominance of psychogenic factors. The possibility therefore arises that the gastric mucosa by its organic changes points to a more basic disturbance of psychiatric importance.

Holtermann and Mähre⁵⁵ in a discussion of gastritis state that gastritis was present in every case of duodenal ulcer and was generally more pronounced and diffused than in gastric ulcer. Gastroscopy is the most reliable diagnostic method and may likewise aid in classification. The gastritis may also be demonstrated roentgenologically. Better information will be obtained when small amounts of contrast medium are spread evenly over the mucosa. Negative roentgenologic findings do not exclude gastritis. Differential diagnosis between hypertrophic gastritis and superficial catarrh and atrophy should not be based on roentgenologic findings.

Hypertrophic Gastritis Simulating Tumor

Pollard and Cooper⁵⁶ made observations of 8 patients in whom stomach x-ray films revealed a filling defect similar to that seen in carcinoma. All the patients were men, and their ages ranged from twenty-two to sixty-five years. In all but 2 cases subjected to gastroscopy, the diagnosis of localized hypertrophic gastritis was established with reasonable certainty by this method of examination. The diagnosis of hypertrophic gastritis and the absence of neoplasm was confirmed in 7 cases by laparotomy and in 6 cases by histologic examination of removed tissue. Since early diagnosis and treatment are essential in the management of gastric neoplasm and operation may be contraindicated in cases of hypertrophic gastritis, it seems important that all these cases be examined gastroscopically before surgery is undertaken. Furthermore, it is perhaps wiser not to depend on a trial of conservative therapy to establish the diagnosis. Localized hypertrophic gastritis is capable of producing a filling defect in the stomach that is difficult to distinguish roentgenographically from that of carcinoma. The symptoms of hypertrophic gastritis may be indistinguishable from those of peptic ulcer or gastric carcinoma. Neither roentgen-ray nor gastroscopic findings are enough in themselves to enable one to distinguish between localized hypertrophic gastritis of the lower regions of the stomach and annular neoplasm in that area.

Hinkel⁵⁷ has reported an interesting case of a localized hypertrophic gastritis simulating the roentgen-ray picture of a tumor. His case revealed

a neoplastic type of filling defect on the lesser curvature of the cardia of the stomach. The tumor-like filling defect was also demonstrated, following pneumogastry, as a soft-tissue mass protruding into the gas bubble. The author discusses the differential diagnosis and briefly cites some of the literature on this subject. He points out that the protruding mass of the pseudotumor is due to a piling up and crowding of the hypertrophic redundant inflammatory mucosa. He emphasizes that achlorhydria is strikingly frequent in this form of gastritis.

Postoperative Gastritis

Browne and McHardy⁵⁸ limit their discussion to chronic postoperative gastritis. They point out the difficulty of a clinical diagnosis following gastrectomy, since this type of gastritis may mimic many gastroenteric lesions. Gastroscopy is suggested. Subclassification is limited to superficial, hypertrophic and rarely atrophic gastritis. The degree of redness of the mucosa was related to the hematopoietic status of the patient. A combination of the first two classifications was frequently encountered, it was severer in the anastomotic area, extending even into the jejunum. An accurate description of the findings is given. Causative factors such as chronic illness, severe trauma, achlorhydria and improper dietary regulations are given instead of the bacteriological factors. The authors give an optimistic prognosis, and after finding roentgen-ray therapy unsatisfactory, they suggest an ulcer regime supplemented by vitamins and liver extract. A case is reported.

Christiansen⁵⁹ believes that postoperative gastritis is a special form of gastritis, differing from other forms in its clinical picture as well as in its pathological and gastroscopic aspects. Gastroscopy reveals an extremely polymorphous picture, which is characterized by a mixture of superficial, hypertrophic, atrophic, erosive and ulcerative lesions. The clinical symptoms differ in many respects from those of peptic ulcer — for instance, the pain is not relieved by food intake. The question of pathogenesis is open to argument, and different theories are discussed.

Gastric Ulcer

Freeman⁶⁰ believes in the gastroscopic control of the treatment of gastric ulcer by duodenal feeding. Although roentgenography is still the standard method of choice in the diagnosis of an ulcer, this author has found a number of ulcers by gastroscopy that were missed by the radiologist, this may have been accounted for by failure of the barium to fill the crater because the floor was already filled with slough of mucus. Therefore, patients who present ulcer symptoms and in whom a negative x-ray examination has been reported should be examined with the gastroscope, and the examination should

be repeated subsequently before cessation of treatment is contemplated

Carcinoma

In commenting on the relation between diet and cancer, Grossman and Ivy⁹¹ raise the question of the possible relations between dietary irritants and gastritis and gastric cancer. They state

Cramer (1934) has observed that the total cancer rate is the same in England and Holland, though the incidence of cancer of the stomach in Holland is approximately twice as great as in England. A subsequent study of Lintott (1939) and Herbert and Bruske (1936) indicated that the Dutch people consume more roughage, hotter food and more spices, spirits and tobacco and have more oral sepsis than the English.

Stout⁹² has made a study of gastric mucosal atrophy and carcinoma of the stomach. This study revealed that mucosal atrophy may appear as early as the third decade and is found with increasing frequency and extent in the succeeding decades of life. In comparable groups of stomachs mucosal atrophy is found in a large number and tends to be more widespread in those with cancer than in those without it. But when one tries to find actual progression from altered mucosal glands, gastric or intestinal in type, cystic or not, distorted or regular, it is realized that it is impossible to tell when there is juxtaposition of carcinoma and mucosal gland, whether the carcinoma is invading the gland or developing from its epithelial cells. In occasional stomachs with carcinoma multiple sections from various areas failed to show epithelial changes in some, whereas others showed only minimal changes. Although atrophy of the gastric mucosal epithelium and cyst formation were present to a greater degree and in larger numbers in stomachs with carcinoma than in comparable stomachs without it, the exact relation between these conditions remained undetermined.

Dailey and Miller⁹³ in a search for symptomless gastric cancer in 500 apparently healthy men of forty-five and over conclude that a survey of the general population in search of gastric cancer is not worth while. Studies of selected groups such as those with pernicious anemia should be expanded, since this seems a profitable approach to the problem.

In a discussion of Krukenberg tumors, Lowman and Kushlan⁹⁴ emphasize the importance of a gastrointestinal survey in cases of ovarian malignancy to determine if possible a primary source of the tumor in the digestive tract. They stress the importance of using every available means of diagnosis in the differentiation of early carcinoma of the stomach and benign gastric ulcer—that is, serial roentgenographic studies and gastroscopy. Gastric ulcer not responding to therapy with rapid and complete healing as demonstrated by x-ray and gastroscopy should be treated as malignant and resected early.

Sweet⁹⁵ believes that the use of the gastroscope is of limited value in cases of carcinoma of the stomach near or invading the cardia. In an occasional case in which the roentgen-ray examination is equivocal, inspection through the gastroscope may help to establish a correct diagnosis.

In a careful analysis of the data available for a ten-year period at the Massachusetts General Hospital, Allen⁹⁶ has found that 14 per cent of the patients treated as having benign gastric ulcer proved to have cancer. These patients responded well to conservative therapy at first, with disappearance of symptoms and a regaining of lost weight. The lesion often appeared to diminish in size on roentgen-ray and gastroscopic examinations. Consequently, Allen is afraid of conservative treatment. He believes that early radical surgery is indicated when a patient appears for treatment with an ulcer of the stomach in the prepyloric or fundal regions. If he is over forty years of age and has had symptoms for less than one year or if his ulcer is over 2 cm. in diameter, the same advice should be given. If the patient is young and has a small lesion or if the ulcer is superimposed on symptoms of more than five years' duration, a more conservative attitude is justifiable. This patient should not be treated in an ambulatory fashion, as is the usual practice in mild or early duodenal ulcer, but should be given the benefit of an adequate hospital regimen. If the ulcer remains even partially unhealed after one month of such therapy or if there is a return of ulceration one month after healing is apparent, the patient should be urged to submit to surgery.

Since the advent of liver therapy, Olson and Heck⁹⁷ had found a notable increase in the number of cases of carcinoma and polyps of the stomach in cases of pernicious anemia. Undoubtedly it is significant that patients who have pernicious anemia now have an indefinite prolongation of life. The processes that are active in the alteration of the gastric mucosa are permitted by this extension of life to continue for many years. This factor is probably the one that is responsible for the increased incidence of polyps and carcinoma of the stomach. Pernicious anemia is a disease of the gastric mucosa as well as a disorder of the hematologic and neurologic systems. Treatment that is sufficient for the maintenance of normal blood may not be adequate to prevent atrophic changes in the gastric mucosa, which in pernicious anemia may not only become atrophic but may produce benign and malignant growths.

In a study of pernicious anemia and the early diagnosis of tumors of the stomach, Rigler, Kaplan and Fink⁹⁷ state that despite the expansion of roentgen-ray diagnosis, the more general use of gastroscopy and the refinement of the methods of examination of the gastric contents and stool, the record is a black one. The over-all salvage of only 2 per cent of the patients afflicted with this disease

or even the survival of 6 per cent, which is the maximum reported, gives a picture of the difficulties involved. The importance of gastroscopy is emphasized in the case of a patient with pernicious anemia and a benign polyp 4 mm in diameter not found on the first x-ray examination but discovered gastroscopically and later confirmed by x-ray. The possibility of the malignant degeneration of a polyp should be particularly brought to mind in cases of pernicious anemia because of the tendency of the latter to develop carcinoma. In 1939, Rigler, Kaplan and Fink⁹⁷ undertook to examine roentgenographically all their patients with pernicious anemia at semiannual intervals. In summary, they state that in a roentgen-ray study of 211 patients with pernicious anemia on whom examinations of the stomach were made on one or more occasions, carcinoma of the stomach was found in 8 per cent and benign polyps in 7 per cent. In an autopsy study, reported elsewhere,⁹⁸ 12 per cent of patients with pernicious anemia were found also to have carcinoma of the stomach. The data presented indicate clearly an etiologic rather than an accidental relation between pernicious anemia and tumors of the stomach. The routine roentgen-ray examination of the stomachs of patients with pernicious anemia has proved to be a valuable procedure resulting in the salvage of some cancer cases that might otherwise not have been saved. Cases were observed illustrating the rapid change from a benign polyp to a cancer, the presence of both benign and malignant tumors side by side, the absence of symptoms in the presence of large tumors and the development from a small, barely detectable lesion to an extensive, inoperable carcinoma.

In a recent editorial, Benedict⁹⁹ states that a more accurate diagnosis can be obtained in the problem of gastric ulcer and carcinoma when all methods of examination are used in a given case than when reliance is placed on incomplete data. Gastroscopic examination supplements x-ray examination, it does not in any sense compete with it. Reliance can be placed on gastroscopic examination only when the method is carried out by an experienced gastroscopist who knows the limitations of the method, the relative blind areas in the stomach and the proper interpretation of his observations. In a recent lecture, Benedict¹⁰⁰ reported his study of 245 proved cases of gastric disease in an attempt to correlate the gastroscopic, x-ray and pathological findings. An analysis was made of 125 cases of proved carcinoma of the stomach in which it was shown that x-ray and gastroscopic examination were equally good in 67 cases and equally doubtful in 3 cases. X-ray examination was more accurate or more helpful in 32 cases, and gastroscopy was more accurate or more helpful in 20 cases. When the lesion was equally accessible to both methods of examination, the analysis indicated the relative

superiority of gastroscopy over radiology in differentiating benign and malignant gastric ulcers. In the same report, 50 cases of proved benign gastric ulcer were analyzed. In 16 of these x-ray and gastroscopy were equally correct, in 9 cases they were equally doubtful, in 21 cases x-ray examination was superior to gastroscopy, and in only 4 cases gastroscopy was superior to x-ray. In both the carcinoma and the ulcer cases, gastroscopic failures were largely due to mechanical difficulties, which accounted for 25 of the 32 cases of x-ray superiority in the carcinoma group and for 17 of the 21 cases of x-ray superiority in the ulcer group. Benedict concludes that gastroscopy is of value in the ulcer-carcinoma problem and that the most accurate diagnostic results are obtained when all methods of study are used in combination.

Benign Tumor

According to Dewey,¹⁰¹ the incidence of benign tumors of the stomach is estimated at 0.5 to 5.0 per cent of all gastric neoplasms. Adenomatous polyps are seven times more frequent in association with atrophic gastritis than in the presence of a normal mucosa. Diagnosis depends on roentgenologic and gastroscopic study, but the final determination is made by histologic examination. Early surgery is the proper treatment.

Gastric Mucosa in Hepatitis

Knight and Cogswell¹⁰² examined by gastroscopy 9 patients with infectious hepatitis in 7 of whom the appearance of the mucosa was found to be abnormal. The area involved was always the anterior portion of the stomach, and in some cases the abnormal appearing areas extended into the fundus. The findings that have impressed these writers as being most distinctly abnormal gave the appearance through the gastroscope of being almost identical with the small aphthous ulcers that are often seen in the mouth. Five patients in this series were observed to have these ulcerations. Further study is essential before any conclusions can be formulated with regard to the relation between the findings in the gastric mucosa and infectious hepatitis.

Hemorrhage

From a study of 112 patients who had had gross bleeding from the upper gastrointestinal tract, Clark¹⁰³ advocates gastroscopic examination after hemorrhage of undetermined origin.

In an article on inflammatory lesions of the upper gastrointestinal tract, Aaron¹⁰⁴ suggests the following criteria for healing of ulcerated lesions of the stomach: complete cessation of all symptoms, maintenance of or gain in weight, persistent absence of occult blood from the feces, disappearance of anemia of the iron-deficiency and essential-factor type, a normal sedimentation rate, roentgenologic evidence of complete healing, and, if it is possible

to obtain it, confirmation by gastroscopy. Only when these studies are repeated over a four-week to six-week period of observation can one be sure that a lesion of the stomach has healed and remained healed and is thus likely to be benign. If this does not occur, the patient is entitled to surgical intervention.

Jankelson¹⁰⁵ has studied 60 cases of hematemesis of unexplained origin. Seven patients died before extensive studies could be carried out. In 3 of them, autopsy did not reveal the source of the bleeding. The other 53 patients had intensive posthemorrhage studies, including roentgen-ray examination in all cases and gastroscopy in 10 cases. In retrospect, Jankelson advocates earlier x-ray study as well as more frequent and earlier gastroscopic examination to demonstrate acute changes in the gastric mucosa, which often heal rapidly without leaving any permanent changes. Acute hemorrhagic gastritis, multiple fissures of the stomach and some gastric ulcers will thus be demonstrated.

Although 50 per cent of cases of chronic seasickness present x-ray evidence of hypersecretion, loss of gastric motility and spasm of the pylorus, as well as thickened gastric rugae in some, Benedict and Schwab¹⁰⁶ state that the gastroscopic picture is usually essentially normal.

PERITONEOSCOPY

- In a report from the Memorial Hospital in New York City, Narancio, Pierson, McNeer and Pack¹⁰⁷ state

Our chief interest in this endoscopic field has been in the determination or recognition of the inoperability of various intra-abdominal neoplasms. One can frequently appreciate the inoperability of some cancers by this examination, but, on the contrary, the resectability can never be ascertained with any degree of certainty. If this fact were universally known, the limitations of the instrument would be accepted and no extravagant claims for its use would be made. The chief indication for its use, in our hands, is the attempted determination of inoperability in borderline cases.

Boehme¹⁰⁸ believes that peritoneoscopy has a definite and valuable place in the field of endoscopy. The enthusiasm for peritoneoscopy varies directly with the skill of the operator. Thus, also, the information gained on examination depends greatly on the skill and experience of the operator. Biopsy of the spleen was performed with some trepidation in 1 case. Only slight hemorrhage was encountered, and this was controlled by cautery. Fibrin foam was held in readiness, and it was intended to apply it to the bleeding surface by introducing it in the jaws of the biopsy forceps. This procedure should add a safety factor to biopsy of the spleen in the future. The indications for the use of peritoneoscopy to complete abdominal diagnosis are discussed. It is a safe, brief, relatively painless and valuable procedure. The anatomical and other limitations are reviewed to aid in careful selection of cases for examination.

Sweet⁵⁶ believes that the use of the peritoneoscope does not assist in the determination of the resectability of a local growth in the cardia or fundus of the stomach. In many such cases the tumor can not be visualized by this means, but when liver involvement or abdominal carcinomatosis is suspected, peritoneoscopy should be carried out so as to avoid performing a major exploration in inoperable cases.

From a study of primary tumor of the liver, Warvi¹⁰⁹ concludes that biopsy is imperative. Peritoneoscopy offers some opportunity to determine operability in addition to obtaining a specimen for microscopic study. Resection of primary tumors of the liver may be indicated in adenomas, cystadenomas, localized solitary carcinomas and hemangiomas, with certain restrictions.

In a recent Cabot case record of the Massachusetts General Hospital¹¹⁰ the value of peritoneoscopy in acute pancreatitis was demonstrated. During the peritoneoscopy the entire peritoneum, anterior gastric wall, small bowel and liver were seen to be covered with small, pale-yellowish implants averaging 2 mm in diameter. Biopsy of one of these implants showed fat necrosis.

Volwiler¹¹¹ believes that under certain conditions in diffuse disease of the liver, aspiration biopsy¹¹² has proved highly satisfactory in diagnosis. When properly used it is easier than peritoneoscopy, but of course the site of selection of the tissue cannot be determined under direct vision. It has the advantage of being a simpler procedure than peritoneoscopy and also of securing a biopsy specimen from deep in the parenchyma of the liver. When carcinoma is suspected, a direct inspection should be made by peritoneoscopy.

Decker and Cherry¹¹³ have found culdoscopy, or the endoscopic visualization of the pelvic organs by the vaginal route, superior to peritoneoscopy in the diagnosis of pelvic disease and in physiologic study. They believe that the procedure is invaluable in the investigation of pelvic tumors, ovarian disease, endometriosis and ectopic pregnancy and is especially helpful in the detailed study of primary and secondary sterility in women.

CASE 32281

PRESENTATION OF CASE

A fifty-nine-year-old Italian woman entered the hospital because of weakness and pain in both arms.

She was apparently well until twenty months before admission, when she had a pelvic operation the exact nature of which was not known, but which was done per vaginam and was apparently a repair of a cystocele. This operation was performed because of a burning sensation on urination. Two months later she developed pain in the left thigh and weakness of the legs, which tended to buckle under her when she climbed stairs. Ten months before entry the pain disappeared, but she noticed ankle swelling that gradually progressed up her legs. The weakness of the legs also progressed, and three months later she could no longer negotiate stairs without help and there was swelling up to the thighs. Two months later, she was seen at another hospital, where an x-ray examination of the chest, a gastrointestinal series, a barium enema, an intravenous pyelogram and peritoneoscopy were reported as negative. During her three-week stay in that hospital, the swelling of the legs decreased and continued to do so on a low-salt diet. She was discharged with a diagnosis of thrombophlebitis. Shortly afterward she began to have sharp pains in the calves and ankles that later progressed up to her hips, back and arms. She obtained some relief with heat and aspirin. At about the same time, she noted the onset of intermittent fever as high as 102°F, with such excessive sweating as to necessitate changing her bedclothes two or three times a night. She also had marked tremors in both hands. One month before entry the patient developed nocturia (three times) and also became anorexic. Her condition remained essentially unchanged until seven days before entry, when there was a sudden onset of pain in the arms, especially at the shoulders, elbows and wrists and in the neck, jaw and back of the head. Concomitantly she noticed marked weakness in both arms. During the year before admission she had lost about 25 pounds.

Her past history was noncontributory. She had borne eight children.

Physical examination revealed an ill appearing

woman who did not move her arms, was perspiring freely and was apparently in pain. The left pupil was larger than the right, but both reacted normally to light. A firm, nontender, 3-cm node was felt in the left axilla. There were dullness and absence of breath sounds at the right base. The liver edge was palpated three fingerbreadths below the costal margin, and a questionable mass was palpated below it. The vagina appeared constricted. No cervix or fundus could be felt. Examination of the arms revealed wasting of the deltoid and biceps muscles and absence of biceps and radial reflexes. The legs showed wasting of the quadriceps muscles, loss of knee and ankle jerks and moderate ankle edema. The only sensory changes were tenderness over the seventh cervical vertebra and over the anterior portion of the left mandible, with anesthesia of the left side of the chin, including the lower lip.

The temperature was 100°F, the pulse 120, and the respirations 24. The blood pressure was 155 systolic, 85 diastolic.

Examination of the blood showed a red-cell count of 4,200,000, a hemoglobin of 10.5 gm and a white-cell count of 7300, with 74 per cent neutrophils and no abnormal cells. Another observer noted the presence of occasional nucleated red cells. The serum phosphorus was 4.3 mg per 100 cc., and the alkaline phosphatase 5.3 Bodansky units. The non-protein nitrogen was 24 mg and the total protein 7.0 gm per 100 cc, with an albumin-globulin ratio of 1.3. The cephalin flocculation test was negative after twenty-four hours and \pm after forty-eight hours. A catheterized specimen of urine gave a +++ test for albumin, and the sediment contained up to 20 white cells per high-power field. The specific gravity of four specimens ranged from 1.012 to 1.022. Two stool specimens were formed, brown and guaiac negative. The spinal fluid was negative except for a protein of 125 mg and a sugar of 120 mg per 100 cc, and 1000 red cells per cubic millimeter.

X-ray examination revealed areas of increased density in the right lower chest, probably involving the middle and lower lobes and consistent with collapse (Fig 1). A small amount of fluid appeared to be present in the right pleural cavity. A plain film of the abdomen showed fixation of the right half of the diaphragm. It was not definite whether the area of density on the right side was above or below the diaphragm.

Despite supportive therapy the patient rapidly failed, becoming increasingly dyspneic and weak. She had constant diaphoresis. Thoracentesis was attempted between the sixth and seventh ribs posteriorly, but no fluid was obtained.

The patient died on the tenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR ALFRED O LUDWIG I should like to begin by looking at the x-ray films

DR. JAMES R. LINGLEY These films show the marked elevation of the right half of the diaphragm, with density in the lower lung field that is consistent with collapse of the lower lobe. There is probably a small amount of fluid in the costophrenic angle. The plain film of the abdomen shows a moderate amount of gas in the colon. There is a shadow beneath the lower border of the liver that could be a gallstone or calcification in a costal cartilage.

DR. LUDWIG Is that not a process in the lung?

DR. LINGLEY I believe that there is collapse of the lower lobe. The diaphragm is elevated, and the elevation could be due to subdiaphragmatic

diagnosis of thrombophlebitis was made. I do not see how anyone can say whether that was the correct diagnosis. It could have caused the symptoms that she presented. It is surprising that a swelling of the legs, supposedly due to circulatory obstruction, decreased on a low-salt diet. The next striking factor in this history is the onset of pains in the calves and ankles, with progression up to the hips. It is my impression that the pains were of neurologic rather than local origin. We know nothing about the condition of the joints at that time, and I think that we must assume that they were normal. About then she developed fever, which continued

FIGURE 1

disease or to collapse of the lung. The films do not help much on that. We also have a film of the cervical spine, which is negative.

DR. LUDWIG It seems to me that the outstanding episode in this woman's illness is the development of pain and increasing weakness of the legs two months before entry, associated at first with rather marked edema. She was studied extensively elsewhere, we do not know what was found, but the

until the time of death. It is necessary to explain the origin of that fever. The first thing to think of is infection, since this woman had a deep-seated thrombophlebitis. I also think of cancer, of which there are no clues, however. Cancer could also account for the fever. In that regard lymphoma should certainly be considered. The tremors I cannot explain, although they may have been due to weakness. There is no indication that this woman had any

acute cerebral accident The final and important part of the history is the sudden onset of pain in the arms, back of the head, various joints and jaw I should be interested to know exactly what the joints looked like

DR JOHN STANBURY The joints were normal

DR LUDWIG I assumed that they were Furthermore, arthritis or rheumatic fever could hardly have produced the picture described

The patient had nocturia, from which I judge that some renal insufficiency was present The history of anorexia and weight loss does not help much They are consistent with any chronic illness, whether due to cancer or to chronic infection The irregularity or the disproportion of the size of the pupils is not helpful to me, because there were no other pupillary abnormalities I should like to know, of course, what that firm, nontender 3-cm node in the left axilla was It seems a little large to be accepted as a normal lymph node The chest signs were not discussed by the roentgenologist, but he raised the question whether the trouble was above or below the diaphragm Judging by later statements in this history, one must certainly consider something above the diaphragm because of the marked dyspnea that developed The fact that the liver edge was three fingerbreadths below the costal margin is an important finding, as is the questionable mass palpated below it I forgot to ask Dr Lingley if he could see that mass in the x-ray film

DR LINGLEY I do not see any mass I think that the liver is enlarged

DR LUDWIG Is the enlargement an intrinsic increase in size, or is the liver depressed by something above it?

DR LINGLEY You can see the lower border fairly well from the splenic flexure of the colon, and the entire liver shadow looks rather large to me

DR LUDWIG The vaginal examination was normal The examination of the arms which showed wasting of the muscles and the absence of biceps and radial reflexes, must also be taken seriously Because of the absence of sensory changes, it seems to me that there must have been some disturbance in the anterior-horn cells or in the anterior roots Without any sensory abnormalities, I do not see how one can assume that this was due to peripheral neuritis or neuronitis The anesthesia on the left side of the chin, including the lower lip, is somewhat difficult to explain, and I believe that it was on the basis of some local interference of the roots of the fifth nerve going to that part of the face I think that the other important finding in the physical examination is the tenderness over the upper cervical vertebrae The wasting of the quadriceps muscle and the loss of knee and ankle jerks probably mean the same thing in the lower extremities as in the upper extremities, namely, that there was some interference in the anterior-horn cells or roots

The laboratory findings, so far as the blood is concerned, help me little There was a moderate degree of secondary anemia The serum phosphorus, the serum phosphatase and the total protein were within normal limits I am not disturbed by the cephalin flocculation test The +++ test for albumin was found in a catheterized specimen, and if it is to be taken seriously, it indicates some type of renal disease Four urine specimens had specific gravities ranging from 1.012 to 1.022 That means that she was still able to concentrate urine relatively well Nevertheless the albuminuria is indicative of renal disease The spinal-fluid findings are quite disturbing Certainly the protein was markedly elevated, the normal upper range being somewhere around 45 mg per 100 cc The sugar value was high, since the normal spinal-fluid sugar ranges from 60 to 70 mg per 100 cc I should like to know what the blood sugar was Incidentally, I cannot think of any neurologic condition that is characterized by an increase in the spinal-fluid sugar Usually such an elevation mirrors a concomitant elevation of the blood sugar Is there a record of the blood sugar?

DR TRACY B MALLORY No blood sugar was recorded

DR LUDWIG We shall have to throw out the finding of high sugar in the spinal fluid, I do not know what it means

I think that we can say definitely that the finding of 1000 red cells per cubic millimeter was not responsible for the 125 mg per 100 cc of protein I should like to know whether the cells were crenated, and whether they appeared immediately at the beginning of the test, or when the last portion of the spinal fluid was withdrawn

DR STANBURY The cells were not crenated and were in the last portion of the fluid

DR LUDWIG In the last phase of this case attention was focused on the right chest and unsuccessful attempts were made to withdraw some fluid, undoubtedly for diagnostic purposes

After putting all this together, the most honest answer is, I do not know-the diagnosis I believe that the woman had thrombophlebitis to begin with Could that have progressed to produce pyelphlebitis? Certainly there is no evidence of pyelphlebitis, which is usually associated with infection in the region of the appendix and is followed by an intermittent spiking temperature, multiple abscesses of the liver and jaundice, which usually runs a rapid course unless the infection is curtailed It is possible that there was an infection in the region of the liver If that were so, one of my guesses would be that there was a subdiaphragmatic abscess I cannot say, however, that there is much evidence of such an abscess Could this patient's symptoms be explained on the basis of multiple venous thromboses? I think that that is possible There is nothing to suggest that the difficulty in the lung was

due to a pulmonary embolus there was no hemolysis or history of chest pains, and no indication of endocarditis or cardiac valvular disease. Finally how can one explain what happened in the spinal canal? The patient could have had a thrombosis or embolus in the spinal canal. It would be extremely unlikely for either condition not to produce a definite myelitis, with a level and with sensory changes that were not present in this case. I have seen one case in this hospital in which there was a high spinal-fluid protein without block, which was due to a hemangioma. I gather that there was no block in the case under discussion. Hemangiomas of the spinal cord, which occur on the posterior surface of the cord, usually produce fairly marked sensory changes. Another possibility is an epidural abscess in the bony structures in the area of the seventh cervical vertebra, with some encroachment on the spinal cord. Whatever happened there apparently happened suddenly. Whether a small abscess rapidly increased in size, or burst or produced some local thrombosis, I do not know. In either event an abscess in the region of the seventh cervical vertebra was probably found. Again, I am quite at a loss to explain the terminal episode in this woman's illness. We are told that she failed rather rapidly, showed increasing dyspnea, and died. This may represent a terminal pneumonic infection, but from what we are given I can draw no conclusion. I do not know why she died.

In summary, although I do not believe that I am close to the diagnosis, I think that this woman had a chronic infection. It is possible that she had multiple septic venous thrombosis or multiple abscesses — one in the region of her liver, followed by a subdiaphragmatic abscess, and another in the region of the seventh cervical vertebra. Cancer is always possible, and cannot be ruled out in this case. If a biopsy on the axillary lymph nodes had been done, much light would have been shed on this case.

DR MALLORY: I think that you should have some additional information, Dr Ludwig.

DR LUDWIG: I do too.

DR MALLORY: A biopsy of the axillary lymph node was made, but the answer was not available at the time the patient died.

A PHYSICIAN: Was a test for Bence-Jones protein done on the urine?

ANOTHER PHYSICIAN: The urine was examined for Bence-Jones protein and was negative.

CLINICAL DIAGNOSIS

Malignant lymphoma

DR LUDWIG'S DIAGNOSIS

Multiple septic thrombophlebitis, with secondary abscess formation (in region of liver and epidurally in cervical region)?

Malignant tumor (origin and type unknown)?

ANATOMICAL DIAGNOSES

Malignant lymphoma involving retroperitoneal tissues and meninges of spinal cord.

Thrombosis of right hepatic vein

Thrombophlebitis of iliac vein, old

PATHOLOGICAL DISCUSSION

DR MALLORY: Our first opinion in the laboratory was that the lymph node removed showed simple hyperplasia. On reconsideration we eventually decided that the diagnosis was giant follicular lymphoma. Autopsy showed an extensive retroperitoneal lymphoma involving the mesentery and the tissues around both kidneys. Histologically this also proved to be lymphomatous but showed no traces of follicle formation. The elevation of the diaphragm on the right must have been largely due to tumor around the right kidney. The liver was enlarged, not because of the few small foci of tumor but because of a thrombosis of the right hepatic vein, with a partial infarction of the entire right lobe of the liver. The spinal cord seemed at first negative, but on more careful examination the meninges were found to be focally infiltrated with tumor. This process was most marked in the region of the cauda, which seemed to account adequately for the weakness of the legs. There was some infiltration in the cervical region, but it hardly seemed enough to explain the severe pains in the arms, neck and head or their sudden development. I think that nerve roots must have been caught in the tumor infiltration at some point that we failed to discover. There was evidence of old thrombophlebitis in the iliac vein.

CASE 32282

PRESENTATION OF CASE

A fifty-year-old chauffeur entered the hospital because of epigastric pain.

The patient was apparently well until a week before admission, when he had an attack of evening "indigestion" accompanied by severe, dull, gnawing, nonradiating epigastric pain ("as if the stomach were twisting"), a feeling of pressure and a great deal of belching. He called his doctor, and was given morphine. The next day the symptoms had ceased. Two nights before entry, he had a similar episode and again received morphine. The night before admission there was a third recurrence of pain, which persisted until the following day despite two injections of morphine. He had no fever, chills, vomiting or nausea. His last bowel movement was one day before entry. His appetite was good until the present illness. There was no previous history of gastric distress, but he had always avoided fried foods and gravy. Six years before entry, the patient had an episode of weakness, at which time an electro-

cardiogram was reported as normal. There was no history of recent weight loss.

Physical examination revealed a drowsy man with constricted pupils who was still suffering from epigastric distress. The pupils responded to light. The tongue was dry and coated with a yellow film. The heart and lungs were normal. The abdomen was somewhat tense but not tender. No masses were felt.

The blood pressure was 130 systolic, 85 diastolic. The temperature was 99.5°F, the pulse 90, and the respirations 20.

Examination of the blood revealed a hemoglobin of 16.1 gm. and a white-cell count of 17,400, with 85 per cent neutrophils. The urine was negative except for a + test for albumin.

A plain film of the abdomen revealed a moderate quantity of gas and fecal material in the colon. In the right midabdomen there was a gas-filled loop of small bowel, which was not dilated. There were calcified lymph nodes just to the right of the lumbar spine. Two ring shadows were seen in the gall-bladder region. When the patient assumed the upright position one of these shadows dropped to the fundus, but the other remained in the region of the cystic duct.

At 2.00 p.m. on the day of admission, the patient was free of pain but still moderately under the influence of morphine. There was minimal residual tenderness over the area of the gall bladder. At 5.00 p.m. there was a recurrence of pain, subjectively located in the upper epigastrium. On palpation the right upper quadrant was much more rigid than the left. Sharp pain was elicited on palpation in the right upper quadrant just lateral to the border of the rectus muscle, and one observer felt a suggestion of a soft mass in that area. Morphine was again administered. By evening the abdominal spasm was limited to this rather sharply defined zone along the right costal margin, where another observer thought that he could feel a mass. The patient felt fairly well, but the temperature had risen to 102°F and the white-cell count to 21,050.

On the second hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. CLAUDE E. WELCH. In essence, this is the history of a fifty-year-old man with repeated attacks of severe epigastric pain that occurred within a week. The discussion of the differential diagnosis may be quickly limited to the gall bladder, pancreas, stomach and duodenum. In other words, was this an acute gall-bladder condition, acute pancreatitis or a perforated peptic ulcer?

The history eliminates the least likely diagnosis, perforated peptic ulcer. The patient had attacks of severe pain at intervals, but between them he was apparently free of distress. This is not the history of perforated ulcer. No mention is made

of a plain film of the abdomen taken with the patient in a sitting posture, probably because the surgeon in charge did not consider perforated ulcer a possible diagnosis.

There is also little in the history to support the diagnosis of pancreatitis, which is usually ushered in by an acute attack of pain that is not remittent. Severe pancreatitis is frequently associated with vomiting. In the later stages, the white-cell count becomes high, although the temperature is likely to remain nearly normal. A blood amylase determination would have been of value so far as this diagnosis is concerned, but none is reported in the record.

One therefore returns to the most probable diagnosis — gall-bladder disease. So far as the exact type of disease is concerned, the intense pain, consisting of repeated steady attacks without nausea and without either chills or jaundice, indicates that there was no common-duct involvement and that the obstruction was in the cystic duct. Additional evidence is supplied by the x-ray film, which shows shadows of stone too large to pass through the cystic duct.

The rapidly rising temperature and the rising white-cell count under bed rest in the hospital suggest that a simple acute cholecystitis progressed to empyema. With this deterioration of the patient's condition operation was obviously indicated at an early stage, because of the impending danger of perforation.

There is no unequivocal evidence whether the gall bladder perforated. With a simple empyema of the gall bladder, a mass should have been easily palpable in a patient of normal size, there is nothing in the history to indicate that this patient was obese. Certainly the gall bladder was large when the x-ray film was taken, since one of the stones changed position.

I therefore believe that the gall bladder perforated after the x-ray film was taken and before the operation was performed. My final diagnosis is acute cholecystitis, with gangrene and perforation of the gall bladder and pericholecystic abscess.

DR. MARSHALL K. BARTLETT. When this patient was seen before operation, our line of reasoning was much the same as that of Dr. Welch. The patient had been so heavily medicated before admission that it was difficult to evaluate the exact status of the process, and it was decided to observe him overnight. By the next day it was obvious that the disease was progressing, and operation was deemed advisable. I did not feel a definite mass at any time.

CLINICAL DIAGNOSES

Acute cholecystitis
Cholelithiasis

DR WELCH'S DIAGNOSES

Acute cholecystitis, with gangrene and perforation of gall bladder and pericholecystic abscess
Cholelithiasis

ANATOMICAL DIAGNOSES

Acute and chronic cholecystitis
Cholelithiasis

PATHOLOGICAL DISCUSSION

DR BARTLETT At operation, thirty-six hours after the onset of the attack, there were a few fresh adhesions to the gall bladder, which was tense, edematous and obviously acutely inflamed. It

contained several large stones. The cystic duct was small. Nothing abnormal was felt in the common duct, which was therefore not explored. The cystic duct and artery were isolated and tied. The gall bladder was removed in the usual manner without particular difficulty. The patient made an uneventful recovery, and was discharged on the eleventh day after operation.

DR BENJAMIN CASTLEMAN The gall bladder that we received in the laboratory was edematous and porky and measured 7 mm in thickness. A large patch of fibrinous exudate was present on the serosal surface, and the mucosa was markedly hemorrhagic and necrotic. There was therefore evidence of both acute and chronic inflammation.

HOSPITALS FACE CRITICAL SITUATION

Most of the hospitals in the Boston area are experiencing great difficulty in getting enough people to care for their patients. This includes graduate nurses, licensed attendants, ward helpers and ward maids.

The salaries of all these groups of people have been advanced to meet the increased cost of living. When all is said and done, the salaries of nurses compare favorably with those paid in government hospitals when it is realized that nurses working in civilian hospitals can choose their place of occupation.

There is no question that there is a shortage of nurses. No one knows just why whether it is

because so many nurses are getting married, whether so many nurses are accepting their privileges under the G I Bill of Rights, whether so many nurses are engaged in private duty, or whether so many nurses are entering service in the hospitals of the Army, Navy, Veterans Administration and Public Health Service. One cannot help wondering whether nurses realize the full seriousness of the situation in relation to the public's health.

The Massachusetts General Hospital had to close 80 of its beds in May, although a few of these were reopened in June. The Massachusetts Eye and Ear Infirmary is facing a serious shortage of nurses and has had to close its children's ward and nursery, emergency children's cases, however, are admitted and cared for in a section of the adult ward.

Hospital trustees, administrators, institutional nurses and employees have done and are doing everything that they can think of to remedy this situation. Little more can be done other than to let everyone, including patients, potential patients, possible employees, physicians, nurses and others, know what the situation is. The matter has now become a community as well as a hospital problem.

LIFE INSURANCE MEDICAL RESEARCH FUND STARTS SECOND YEAR

It is generally agreed that fundamental research in science is useful and deserving of support. It is also well known that such research has become increasingly expensive and that the funds available for that purpose have not kept pace with the growing needs. Because the prospects of sustaining and expanding research in the physical and biologic sciences by private funds are steadily diminishing, new sources for support of activities in these fields have been sought. The many useful results achieved by governmental support of scientific research connected with the war effort have stimulated activity in favor of inaugurating a system whereby the physical and biologic sciences and scientists in these fields could receive appropriate aid from governmental funds. Most scientists, however, suspect that such support implies political dictation and control, as well as an unnecessary amount of red tape. They therefore prefer other sources of funds, if they

can be provided. Those who hold that opinion believe that all possible private sources should be explored and that these agencies should be encouraged to provide the necessary funds, free of all encumbrances.

With respect to research in the medical sciences, its primary and long range purpose, broadly speaking, is to keep the greatest number of people in the best of health for the longest time. That purpose coincides exactly with the objectives of all life-insurance companies. To them the accomplishment of this purpose means increasing returns in terms of dollars and cents. It is therefore not surprising that executives of the majority of the large life-insurance companies in the United States and some in Canada have pooled funds for the support of basic research in medical problems and have entrusted these funds to an organization called the Life Insurance Medical Research Fund. The advisory council of this fund includes a group of medical investigators from different universities, most of whom have had considerable experience with the administration of research funds.

The first annual report of the Life Insurance Medical Research Fund, that for the year 1945, has recently been mailed to the one hundred and forty-eight sponsoring companies in the United States and Canada. During that time \$126,525 was earmarked for grants already approved for eight research projects underway at six medical schools. Because of conditions associated with the termination of the war, only 25 per cent of the annual contributions of the various member companies was called for in 1945, but it is the intention of the fund to call for full contributions, amounting to approximately \$580,000, in 1946. The chairman of the Board of Directors of the Fund states that the program holds much promise of good for both policyholders and the general public. The type of research that is being supported is fundamental in character and concerns, among other things, investigations into the basic causes of rheumatic fever, hypertension and arteriosclerosis. It is fully appreciated that tangible results in such researches must not be looked for too soon, and it is implied that the Fund will continue to support plans of research on a long-term basis.

There are many other private groups that would also benefit by developments along similar lines. Thus, the manufacturers of pharmaceuticals and industrialists in general have long-range interests in this field, and their promotion of fundamental research by the financial support of teachers and investigations in medical sciences could not fail to be a good investment. They should be encouraged to follow the lead of the life-insurance companies.

MASSACHUSETTS MEDICAL SOCIETY

SUBCOMMITTEE ON VETERANS' AFFAIRS, COMMITTEE ON POSTWAR PLANNING

The Subcommittee on Veterans' Affairs, composed of G. Philip Grabfield, chairman, Victor G. Balboni, George P. Denny, Alexander Marble and George F. Wilkins, has been enlarged to include representatives of all the district medical societies. The representatives thus far appointed are as follows:

Barnstable Sheldon L. Hunt, Yarmouth Port
Berkshire Franklin K. Paddock, Pittsfield
Bristol North Leonard W. Hill, Attleboro
Bristol South Merrill F. Gardner, Fairhaven
Essex North Louis B. Simard, Haverhill
Essex South Frank P. Morse, Jr., Salem
Franklin Spencer C. Flo, Greenfield
Hampshire Stephen Brown, Northampton
Middlesex East William M. Gowen, Melrose
Middlesex North Thomas J. G. Tighe, Lowell
Middlesex South John C. McGirr, Belmont
Norfolk Leo R. Desmond, Dorchester
Norfolk South Ensio K. F. Ronka, Wollaston
Plymouth William M. Carr, Whitman
Suffolk Charles H. Bradford, Boston
Worcester Thomas Hunter, Shrewsbury

Any veteran physician with problems or suggestions in relation to veterans' affairs should communicate with his district representative or the chairman.

G. PHILIP GRABFIELD, *Chairman*

MISCELLANY

PUBLIC-HEALTH CONFERENCE IN CHINA

News has been received from Lieutenant Colonel Merrill Moore, M.C., A.U.S., to the effect that he took an active part in the organization of the first public-health conference to be held in China during the past ten years. The conference was sponsored by Major General Robert B. McClure, commanding general of the Nanking Headquarters Command, United States Army Forces, and by General Ho Yin-Ching, supreme commander of the Chinese Army, and was held on Saturday, April 20, in the Assembly Hall of the Supreme Headquarters of the Chinese Army at Nanking. The program comprised sixteen addresses, the majority in Chinese, having to do with various aspects of preventive medicine and hygiene.

BOOKS RECEIVED

The receipt of the following book is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

What to Do about Vitamins By Roger J. Williams, Ph.D., director of the Biochemical Institute, University of Texas 8°, cloth, 56 pp. Norman, Oklahoma: University of Oklahoma Press, 1945. \$1.00

This popular manual discusses the necessity of vitamins and minerals in the diet and how they may be secured in adequate amounts. The text is illustrated with tables, graphs and charts for easy reference. Appended to the text is an interesting table of the vitamin content of the common foods, both vegetable and animal.

Total War and the Human Mind: A psychologist's experiences in occupied Holland By A. M. Meerloo, M.D., F.R.S.M. 8°, cloth, 78 pp. New York: International Universities Press, Incorporated, 1945. \$1.75

In this book Dr. Meerloo has drawn on his experiences of two years in occupied Holland and discusses such themes as mass reaction to German occupation, Hitler's psychological weapons, the psychology of radio propaganda and how the body is affected by fear.

Pharmaceutical Calculations By Willis T. Bradley, A.M., and Carroll B. Gustafson, Ph.C., A.M. 8°, cloth, 283 pp. Philadelphia: Lea and Febiger, 1945. \$2.75

This manual is based on the *Pharmaceutical Arithmetic* of Professor Theodore J. Bradley but is substantially a new work, since it includes theoretical discussions and explanations preceding examples and practice deliberately excluded from the original work.

Much new material has been added, including a simplified equation for converting centigrade and Fahrenheit scales, a new approach to ratio and percentage and dilution problems consistent with the *Pharmacopoeia* and an original treatment of isotonic problems.

It includes careful definition of terms and is intensely practical in its application. Appendices contain related matter on problems in general chemistry, weights and volumes of gases, proof strength, emulsions, solubility ratios and tables of epitonic equivalents, dilution, weight and volume of water and atomic weights.

This small volume should prove of value not only to students and teachers of pharmacy but also to pharmacists, chemists, physicians, nurses and all others confronted with the problems of arithmetical problems in pharmacy. It is recommended for reference purposes to medical and allied libraries.

Lights Out By Baynard Kendrick. 8°, cloth, 240 pp. New York: William Morrow and Company, 1945. \$2.50

This is the story of a blinded soldier and his conditioning in Army hospitals for a normal everyday life.

The Male Hormone By Paul de Kruif. 8°, cloth, 243 pp. New York: Harcourt, Brace and Company, 1945. \$2.50

DeKruif, in another of his popular books on medical subjects, narrates the story of the long struggle to isolate the male hormone until its discovery by the chemists, Ruzicka and Bubenandt, in 1935, who later were awarded the Nobel prize for their work. The author then relates in plain language the use of testosterone in revitalizing men suffering from poor health due to sexual insufficiency.

Your Hair and Its Care By Oscar I. Levin, M.D., and Howard T. Behrman, M.D. 12°, cloth, 184 pp. New York: Emerson Books, Incorporated, 1945. \$2.00

The authors are dermatologists who have written in plain language an up-to-date popular manual on the human hair. They tell what to do to save and beautify the hair and to stimulate healthier growth and discuss such conditions as baldness of various types, dandruff, infections of the scalp, abnormal types of hair and the effects of occupations on the hair.

Moderne Esstherapie By Rudolf Stodtmeister and Peter Büchmann. With introductory remarks by Professor Dr. R. Siebeck, of Heidelberg, and Professor Dr. L. Heilmeyer, of Jena. 8°, cloth, 120 pp. Ann Arbor: J. W. Edwards, Incorporated, 1944. \$3.75. Published and distributed in the Public Interest by Authority of the Alien Property Custodian under License No. A-492.

This monograph in German has been considered of sufficient importance to be reproduced by lithoprinting from the original Stuttgart edition of 1943. This fact alone speaks well for the importance of the work. About half the text discusses the use of iron in the treatment of the anemias, including the pernicious and aplastic types. The first two chapters have to do with the role of iron in the human organism and iron resorption. These are followed by a brief consideration of the general indication of iron in treatment and then by a section on the clinical use of iron in the anemias. The last short chapter is miscellaneous in character, discussing such topics as blood transfusion and iron therapy, iron and arsenic, iron preparations, length of treatment, intravenous use and liver treatment. The text is compact and in simple German. This monograph should be in all medical libraries and on the shelves of all physicians specializing in blood diseases.

THE SURGERY OF THE INNOMINATE ARTERY*

GUSTAF E. LINDSKOG, M.D.†

NEW HAVEN, CONNECTICUT

THE first recorded operation on the innominate artery was performed by Valentine Mott of New York on May 11, 1818. Ligation of this vessel in an attempt to cure a traumatic subclavian aneurysm was followed by wound sepsis, secondary hemorrhage and death. Such was the fate of all subsequent surgical attempts in the preaseptic era until the twentieth recorded case, in which a successful ligation for subclavian aneurysm was performed on May 15, 1864, by Andrew Smyth,¹ of New Orleans. This patient was younger, and fate was kinder. Recovery ensued after a terrifying series of hemorrhages, for the treatment of which metallic shot was repeatedly introduced into the suppurating wound. The eventual result was satisfactory, with arrest of symptoms until a recurrence and reoperation caused death eleven years later. Coppinger,² of Dublin, was the first European surgeon successfully to accomplish this formidable ligation. His operation was performed in 1893.

With the advent of antiseptic and finally aseptic technics and with the development of suitable anesthesia procedures, cases accumulated and relatively greater success was enjoyed. In 1905, Sheen³ was able to collect 36 cases, including one of his own, which was the eighth successful ligation. In 1915, Thompson's⁴ review added 16 cases. The latest complete survey of the literature was made by Greenough⁵ in 1929. His report is characterized by accuracy and completeness. It comprises 91 cases and includes ligations, simple sutures, excisions and attempted ligations, besides reporting one personal success. In this series the operative mortality rate was 56 per cent, but in the most recent 25 cases it was only 16 per cent. I have re-examined the available literature and have collected 18 new cases, all of which have appeared since Greenough's summary.

INDICATIONS FOR OPERATION

Ligation of the innominate artery has been performed for four indications: recent wounds of this vessel and its two major branches, 11 cases, traumatic

aneurysm of the innominate, subclavian and carotid arteries, 20 cases, spontaneous—usually syphilitic—aneurysm of these vessels, 75 cases, and control of remote bleeding, 1 case. The indications and results are listed in Table 1. A certain latitude must be permitted in the interpretation of many of the operative reports. Some obscurity in description is comprehensible when one considers the inadequacies of anesthesia, lighting and exposure that hampered the earlier cases. Doubtless some fatal cases have never been reported.

in the literature, but probably few successful cases have so failed, so that the statistical results must be weighted on the favorable side.

There can be no question of the propriety of and necessity for operation in traumatic lesions of the innominate artery and its bifurcation. The situation is urgent, and many of these patients do not survive the immediate injury, which is usually due to a gunshot, shrapnel or stab wound. A most interesting case of transverse rupture of the innominate artery with an intact chest has been reported.⁶ This patient died without benefit of surgery, and the case is not included in the present series.

*Presented at the annual meeting of the New England Surgical Society, Boston, February 6, 1946.

†Associate professor of surgery, Yale University School of Medicine.

BOOKS RECEIVED

The receipt of the following book is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

What to Do about Vitamins By Roger J. Williams, Ph.D., director of the Biochemical Institute, University of Texas, 8°, cloth, 56 pp. Norman, Oklahoma: University of Oklahoma Press, 1945. \$1.00.

This popular manual discusses the necessity of vitamins and minerals in the diet and how they may be secured in adequate amounts. The text is illustrated with tables, graphs and charts for easy reference. Appended to the text is an interesting table of the vitamin content of the common foods, both vegetable and animal.

Total War and the Human Mind: A psychologist's experiences in occupied Holland By A. M. Meerloo, M.D., F.R.S.M. 8°, cloth, 78 pp. New York: International Universities Press, Incorporated, 1945. \$1.75.

In this book Dr. Meerloo has drawn on his experiences of two years in occupied Holland and discusses such themes as mass reaction to German occupation, Hitler's psychological weapons, the psychology of radio propaganda and how the body is affected by fear.

Pharmaceutical Calculations By Willis T. Bradley, A.M., and Carroll B. Gustafson, Ph.C., A.M. 8°, cloth, 283 pp. Philadelphia: Lea and Febiger, 1945. \$2.75.

This manual is based on the *Pharmaceutical Arithmetic* of Professor Theodore J. Bradley but is substantially a new work, since it includes theoretical discussions and explanations preceding examples and practice deliberately excluded from the original work.

Much new material has been added, including a simplified equation for converting centigrade and Fahrenheit scales, a new approach to ratio and percentage and dilution problems consistent with the *Pharmacopoeia* and an original treatment of isotonic problems.

It includes careful definition of terms and is intensely practical in its application. Appendices contain related matter on problems in general chemistry, weights and volumes of gases, proof strength, emulsions, solubility ratios and tables of epitonic equivalents, dilution, weight and volume of water and atomic weights.

This small volume should prove of value not only to students and teachers of pharmacy but also to pharmacists, chemists, physicians, nurses and all others confronted with the problems of arithmetical problems in pharmacy. It is recommended for reference purposes to medical and allied libraries.

Lights Out By Baynard Kendrick. 8°, cloth, 240 pp. New York: William Morrow and Company, 1945. \$2.50.

This is the story of a blinded soldier and his conditioning in Army hospitals for a normal everyday life.

The Male Hormone By Paul de Kruif. 8°, cloth, 243 pp. New York: Harcourt, Brace and Company, 1945. \$2.50.

DeKruif, in another of his popular books on medical subjects, narrates the story of the long struggle to isolate the male hormone until its discovery by the chemists, Ruzicka and Butenandt, in 1935, who later were awarded the Nobel prize for their work. The author then relates in plain language the use of testosterone in revitalizing men suffering from poor health due to sexual insufficiency.

Your Hair and Its Care By Oscar L. Levin, M.D., and Howard T. Behrman, M.D. 12°, cloth, 184 pp. New York: Emerson Books, Incorporated, 1945. \$2.00.

The authors are dermatologists who have written in plain language an up-to-date popular manual on the human hair. They tell what to do to save and beautify the hair and to stimulate healthier growth and discuss such conditions as baldness of various types, dandruff, infections of the scalp, abnormal types of hair and the effects of occupations on the hair.

Moderne Eisen Therapie By Rudolf Stodtmeister and Peter Büchmann. With introductory remarks by Professor Dr. R. Sicbeck, of Heidelberg, and Professor Dr. L. Heilmeyer, of Jena. 8°, cloth, 120 pp. Ann Arbor: J. W. Edwards, Incorporated, 1944. \$3.75. Published and distributed in the Public Interest by Authority of the Alien Property Custodian under License No. A-492.

in the literature, but probably few successful cases have so failed, so that the statistical results must be weighted on the favorable side.

There can be no question of the propriety of and necessity for operation in traumatic lesions of the innominate artery and its bifurcation. The situation is urgent, and many of these patients do not survive the immediate injury, which is usually due to a gunshot, shrapnel or stab wound. A most interesting case of transverse rupture of the innominate artery with an intact chest has been reported.⁶ This patient died without benefit of surgery, and the case is not included in the present series.

*Presented at the annual meeting of the New England Surgical Society, Boston, February 6, 1946.

†Associate professor of surgery, Yale University School of Medicine.

The problem of syphilitic or nonspecific aneurysm — hereafter called "spontaneous aneurysm" — calls for more detailed consideration and evaluation of data. Practically all these patients have had diffuse arterial and complicating visceral disease. They have an average age (forty-seven years) older than that (twenty-eight years), in the traumatic cases, and the danger of concomitant visceral complications is consequently greater. The incidence of therapeutic failure, especially after simple ligation, is higher in these cases than in the traumatic cases. Yet the life of a patient afflicted with such an aneurysm is usually a miserable one because of pressure symptoms, which include severe pain, dysphagia, hoarseness and dyspnea, and there is always the ominous threat of rupture into the pleural cavity or trachea or through the skin as a terminal event.

A few reported cases with small aneurysms in the third subclavian area, because of their small size and position, the presence of brachial pain and the absence of clinical syphilis, are reminiscent of aneurysm due to cervical rib. If so, they hardly constitute a proper indication for the operation as performed, since this type of case does not have a tendency to progression and is satisfactorily handled by local surgery.⁷

METHODS OF TREATMENT

The ideal treatment of an aneurysm, whether traumatic or spontaneous, is either a Matas end-aneurysmorrhaphy or proximodistal ligation and excision of the sac.⁸ In the case of the innominate artery, the Matas operation does not lend itself to practical application, and there is no record of its deliberate use. Complete isolation and excision of the sac have been accomplished in only 3 cases, in all of which they were successful. Resort to the simpler procedure of ligation in continuity has been the rule, owing to technical difficulties or to the patient's condition. Proximal ligation of the innominate artery, with ligation of the carotid and subclavian arteries distal to the aneurysm — the so-called "triple operation" — has been performed more frequently than has radical excision, and the results have been better than those of proximal ligation alone.⁴ Better surgical technic and more favorable operative conditions may have contributed to this difference.

In the case to be reported, a preliminary ligation of the common carotid artery was performed to test the cerebral circulation, promote the development of collaterals and prevent subsequent cerebral embolism or propagating thrombosis following direct operative trauma to the aneurysmal sac. Cerebral complications (Table 2) are reported to have caused postoperative death in 9 cases, and temporary disability in a few others. The average age in the fatal cerebral cases was 40.0 years, as compared with 42.5 years for the entire series. These

facts suggest that the inherent vascular pattern is of more importance than the age factor.

Not a single case has been reported in which gangrene of the upper extremity followed ligation of the innominate artery, a fact that emphasizes the abundant collateral vascular pathways in the shoulder girdle and axilla (intercostal-subscapular). The

TABLE 2 Cause of Death

occurrence of late ischemic pain, paresthesia and muscular weakness in the arm, however, has occasionally been noted and quite generally disregarded from the therapeutic standpoint. No mention has been made in recent years of the postoperative use of sympathetic block or dorsal sympathectomy. Although aneurysm of the innominate artery frequently produces Horner's syndrome on the right, there is recorded evidence in some cases that a sympathetic release with vasodilatation occurs in the vessels of the right upper extremity within twelve to twenty-four hours after operation. This phenomenon was noted in my patient, who has complained of no ischemic symptoms in the arm since operation.

In view of the technical difficulties connected with exposure of the innominate artery and the high mortality in the earlier cases, various indirect or simpler therapeutic approaches for aneurysm of this artery have been devised and tried. One is the application of the wiring technic, which has been associated with uncertain results and with the complications pertaining to this method in other vessels.⁹ A second is the technic of Brasdor-Guinar — namely, ligation of the subclavian and carotid arteries distal to the aneurysmal sac. With the use of this method, long-term cures of five to twenty-one years have been reported by Baldwin,¹⁰ Schwyzer,¹¹ DaCosta (cited by Rundle¹²) and others. This procedure has been condemned by some authors, but analysis of the reports suggests that there is some prospect of relief or cure when a more radical approach is contraindicated by diffuse aortic disease, the patient's age or his general condition.

Finally, innominate aneurysm has been treated by the creation of an arteriovenous fistula between the common carotid artery and the jugular vein, with an end-to-end technic, as first suggested by Babcock. McCarthy¹³ has reported 8 such cases,

TABLE 3 *Successful Cases of Ligation of Innominate Artery for Aneurysm*

SURGEON	YEAR REPORTED	YEAR OF OPERATION	SEX	AGE	PATHOLOGIC LESION	TYPE OF INCISION	ARTERY OR ARTERIES LIGATED	REMARKS	LAST REPORT
Burrell (Greenough ⁵)	1895	1895	M	4	Spontaneous aneurysm (subclavian and innominate)	Resection of portion of sternum	Innominate	Discharged from hospital on 73rd day cardiac death on 104th day

Sargent (Greenough ⁵)	1911	1909	F	67	Spontaneous aneurysm (bifurcation)	Resection of manubrium	Innominate and carotid	Transient hemiplegia on 10th day	Died in 1911 of nephritis and pneumonia sac obliterated at autopsy
Kimura (Greenough ⁵)	1913	1908	M	46	Spontaneous aneurysm (bifurcation)		Innominate carotid and subclavian	Cured	Well in Apr., 1910
Ballance (Greenough ⁵)	1918	1918	F	60	Spontaneous aneurysm (innominate) (syphilitic)		Innominate		Died on June 5 1921 sac occluded at autopsy
Halsed (Greenough ⁵)	1926	1907	M	61	Spontaneous aneurysm (bifurcation)		Innominate artery (later band to carotid)	Pulsation ceased	Death from pneumonia on Jan 1 1908
Lessner (Greenough ⁵)	1928	1914	M	—	Traumatic aneurysm (innominate)	Supraclavicular	Innominate	Radial pulse returned before discharge	Well
Flint (Greenough ⁵)	1928	1927	M	7	Traumatic aneurysm (bifurcation)	Excision of of manubrium	Innominate and subclavian	Aneurysmal sac packed	Well 5 mo later poor vision of right eye husky voice.
Greenough (Greenough ⁵)	1929	1924	F	48	Spontaneous aneurysm (bifurcation)	Sternoclavicular disarticulation	Innominate carotid and subclavian	Wound sepsis	Well in Apr 1925
Miller Dolbey and Ballance ¹⁸	1934	1925	M	74	Spontaneous aneurysm (innominate) (positive serologic reaction)	Resection of clavicle and manubrium	Innominate	Subsequent ligation of carotid and subclavian arteries in 1925	Recurrence with rupture and death in Oct 1933
Scouttar ¹⁹	1934	1933	F	62	Spontaneous aneurysm (innominate) (negative serologic reaction)	Supraclavicular	Innominate and subclavian	Traumatic hemiparesis at 7 mo	Well
Rock (Rundle ¹²)	1937	1936	F	49	Spontaneous aneurysm (innominate) (positive serologic reaction)		Innominate carotid and subclavian		Living (with paresis) 3 yr later
Edwards (Rundle ¹²)	1937	1935	F	64	Spontaneous aneurysm (innominate)		Innominate	Recurrence (see next case)	
Rock (Rundle ¹²)	1937	1936	F	64	Recurrence (see previous case)	Sternotomy	Innominate carotid and subclavian (excision of sac)		Well in 1937
Matas ⁸	1940	Not stated	Not stated	Not stated	Spontaneous aneurysm (innominate)		Innominate band		Result not stated
		Not stated	Not stated	Not stated	Spontaneous aneurysm (innominate)		Innominate band		Result not stated
Meade ²⁰	1941	1936	F	65	Spontaneous aneurysm (innominate and subclavian) (negative serologic reaction)	Supraclavicular	Carotid and subclavian (fascial strips)	Pulsation persisted	Improved
Elkin ¹⁵	1945	1945	M	25	Traumatic arteriovenous aneurysm (innominate)	Resection of clavicle and manubrium	Innominate (also right innominate vein)		Well in May 1945
Lindskog	1946	1945	M	27	Traumatic aneurysm (innominate)	Section of clavicle and manubrium	Innominate	Preliminary carotid ligation	Well in 1946

all with positive serologic reactions at the time of operation. There were 2 operative deaths, one apparently due to anesthesia and the other to embolism, and 2 later deaths, one at five weeks from myocardial failure and the other at four weeks from rupture of the aneurysm. Four patients survived, 1 for more than four years, and 2 of them were able to resume work. These results and the generally recognized deleterious effect of a large arteriovenous fistula seem to make some other procedure a wiser choice.

THE SURGICAL APPROACH TO THE INNOMINATE ARTERY

The earliest operations on the innominate artery were carried out through a cervical or supra-clavicular muscle-cutting incision, of which the pro-

section or resection. A median section of the manubrium carried through to the second interspace, with section of the right clavicle in its medial third, gave an adequate exposure and a good functional result in my case. Elkin¹⁵ has described the resection type of approach in detail.

In 107 reported cases of ligation or suture of the innominate artery, the immediate operative mortality was 54 per cent. Two of Greenough's cases are not included, since they represent incomplete attempts with survival. Since 1900 there have been reports of 61 cases, with 19 postoperative deaths, a mortality of 31 per cent. The principal causes of death are summarized in Table 2. It is evident that complications of wound sepsis, including mediastinitis, empyema, pneumonia and hemorrhage, have caused the largest group of fatalities. Acci-

TABLE 4 Other Cases of Ligation of Innominate Artery for Aneurysm Since 1929

SURGEON	DATE OF REPORT	DATE OF OPERATION	SEX	AGE	PATHOLOGIC LESION	TYPE OF INCISION	ARTERY OR ARTERIES LIGATED	REMARKS	RESULT

totype is Mott's. This has been adequate in some cases, particularly when the lesion was distal to the innominate artery and when the latter was at a high level.

The first mention of clavicular resection is in Cooper's case report cited by Greenough.⁵ In 1895, Burrell¹⁴ of Philadelphia first resected a portion of the sternum in this connection, and his patient survived ligation. It seems clear that adequate and safe exposure for surgery of the innominate artery demands some type of clavicular and manubrial

dissection of technic follow in importance, after which come cerebral complications. Age appeared to have little or no relation to prognosis in this series, since the average stated age in the fatal cases was 42 years, whereas it was 43 years in the surviving cases.

ARTERIOVENOUS FISTULA

There are 3 recorded cases in which an arteriovenous fistula was treated by surgery of the innominate artery. Holman⁸ in 1927 reported a case in which a subclavian arteriovenous aneurysm was

ruptured during dissection, necessitating ligation of the proximal innominate artery as an emergency procedure. The patient recovered and was apparently cured. Lexer's¹⁶ patient had an aneurysmal varix of the innominate artery and left innominate vein following a stab wound. A transvenous arterial suture was performed, but death occurred from streptococcal sepsis. Elkin¹⁵ in 1945 reported a case of fistula between the artery and both innominate veins. This fistula, which also followed a stab wound, was treated by ligation and section of the right innominate vein and double ligation of the artery. The patient made a good recovery.

No discussion of surgical procedures involving the innominate artery is complete without mention of the recent work of Blalock and Taussig.¹⁷ In an attempt to increase the volume of pulmonary circulation in cases of congenital pulmonic atresia or stenosis, the normal innominate artery has been divided and the proximal end anastomosed to one of the pulmonary arteries.

CASE REPORT

A 27-year-old man was admitted by air transport to a United States naval hospital on August 30, 1945, with a chief complaint of severe pain in the right chest and swelling in the right side of the neck. On May 24, he had been injured by shrapnel from enemy air bombardment on Ie Shima, sustaining multiple small wounds of the right forearm, left foot and right shoulder and a small, sucking wound of the right supraclavicular region. He was rendered immediately unconscious but regained consciousness on the second day without major surgical intervention. He was aphonic for 10 days, had difficulty in vision for 1 week and noted a prominent mass in the lower right side of the neck. The voice improved gradually. On June 12, a bruit was discovered in the right supraclavicular region, and a roentgenogram of the chest showed an enlarged superior mediastinal shadow on the right side. On July 13, the patient had sudden, excruciating pain in the right side of the chest and neck, increased swelling of the mass and painful swallowing, even of liquids. This episode left a sequel of recurring severe pain in the sub-sternal region and right shoulder and frequent headaches. The pain required a routine administration of morphine.

Physical examination on admission revealed a chronically ill man. The face and lips appeared slightly pale and cyanotic. The right palpebral fissure was narrowed, and the pupil was small. The voice was high pitched, and there was a paralysis of the right vocal cord. The trachea was deviated to the left because of a large visible and palpable mass deep in the supraclavicular and jugular region. The mass pulsated during systole, but there was no definite thrill or bruit. The carotid and radial pulses were palpable bilaterally and about equal in volume. Simultaneous brachial blood pressures were 116/80 on the right and 114/75 on the left. There were small, healed wounds of the right wrist, right anterior deltoid region, right supraclavicular region and left foot. The direct measurements of venous pressures in the antecubital fossae were right, 190 mm. of saline solution and left, 185 mm., with free respiratory excursions.

Laboratory studies revealed a negative Kahn reaction and a normal urine. The hemoglobin was 14.5 gm. per 100 cc., and the white-cell count 9000.

A roentgenogram of the chest demonstrated a diffuse widening of the superior mediastinal shadow, continuous with the ascending aorta. The trachea was narrowed and displaced toward the left. There was an irregular, radio-opaque foreign body in the left chest just above the aortic arch. A diagnosis of traumatic aneurysm of the innominate artery from a shrapnel wound was made.

Complete bed rest was enforced. Digital compression of the right carotid artery above the mass in the neck for 5 minutes hourly was begun on September 4. On September 19, ligation of the right common carotid artery was carried out just

proximal to its bifurcation, under local anesthesia. This procedure resulted in a 3-day period of nausea and vomiting but no paresis of the left extremities and no change in blood pressure. On October 3, under intratracheal cyclopropane anesthesia, a trans-sternal anterior mediastinotomy was performed, with ligation of the proximal innominate artery. An incision was made with a horizontal arm just above and parallel to the median half of the clavicle, a vertical component over the midline sternum and a shorter horizontal component over the right 3rd costal cartilage. The proximal portion of the 2nd right costal cartilage was excised, the sternal body was retracted slightly at this level, and the manubrium was split vertically with a Gigli saw introduced from above. The right clavicle was divided. By prolonged and difficult dissection in the densely scarred mediastinal connective tissue, the right and left innominate veins and superior vena cava were mobilized. Both had been displaced and flattened by a large fusiform dilatation of the innominate artery. By dissecting below and above the left innominate vein, a short but relatively normal proximal portion of this artery was freed and a braided linen umbilical tape was passed about it. Temporary occlusion of the vessel resulted in an obliteration of the right radial pulse. The ligature was secured, and a braided-silk ligature was placed above it. The chest was closed with wire sutures to the clavicle and sternum. A rubber-slip drain was left in the wound for 48 hours because of troublesome oozing, which had been particularly noticeable during the initial stages of the chest-wall incision.

Penicillin was given immediately after operation and continued during the 1st week. Early convalescence was complicated by restlessness, euphoria, disorientation, a rapid pulse and elevation of the systolic blood pressure to 150 or 170. The right arm and hand were cool and pale until the morning of the 2nd postoperative day, when warmth and superficial vasodilatation were observed. On the 3rd day, a loud, continuous murmur was heard in the pulmonic area and over the great vessels of the left neck, but only faintly on the right side. This gradually subsided and disappeared. The wound healed well.

A written communication from the patient in December, 1945, indicated continuing improvement, with complete relief of pain and sensations of pressure. There was still some non-pulsating fullness in the clavicular region.

SUMMARY

The literature on the subject of surgery of the innominate artery is reviewed, and the indications for and the technic and results of operation are discussed.

Eighteen cases have been added since a review by Greenough in 1929, and a total of 107 cases of ligation, excision or suture of the innominate artery, with an operative mortality of 54 per cent, are recorded.

Since 1900 there have been 61 cases, with a mortality of 31 per cent.

Nineteen cases of survival after surgery for innominate aneurysm, including the present case, are tabulated. A report of this case is presented.

AN OUTLINE FOR THE TREATMENT OF SEVERE BURNS*

STANLEY M LEVENSON, M D,† ROSS W. GREEN, M D,‡ AND CHARLES C LUND, M D§

BOSTON

AT THE end of a three-year study of burns at the Boston City Hospital, the following outline of directions for their care has been prepared for the guidance of the hospital staff. This outline has been available at the hospital since July 1, 1945.

DUTIES OF THE ACCIDENT-FLOOR PERSONNEL

Take temperature, pulse, blood pressure and respiration. Remove clothing and place patient on sterile sheet. Cover with sterile sheet.

Inspect area of burn and plot on a Boston City Hospital Burn Diagram.* Fill out diagram and make careful estimate of area burned. Order a normal dose of morphine if patient is conscious and in pain and not intoxicated.

Send to Shock Room if patient is in shock, if area is 25 per cent or more or if there is any sign of respiratory-tract injury, such as hoarseness, cough or dyspnea.

Send all other cases to operating floor.

Notify a surgical service concerning the case, giving all data found on examination above. All patients should be admitted to a surgical service except those with respiratory-tract injury only. The latter group should be admitted to a medical service.

Notify the Aural Service of all respiratory-tract injuries for aural consultation.

DUTIES OF THE SURGICAL SERVICES

See patient at once. Shock may be expected shortly, if not already present, in cases of infants up to six years old with an 8 per cent burn or more and children and adults with a 15 per cent burn or more.

General

(Occasional sick or very feeble patients may have shock with smaller burns.) All burns of these extents should have prompt intravenous treatment even if the temperature, pulse, respirations, blood pressure and hemoglobin level are normal. Do hemoglobin and urine examinations (catheterize if necessary). Repeat blood-pressure and pulse determinations every half-hour. Record all findings.

*From the Burn Assignment of the Surgical Service, the Thorodike Memorial Laboratory and the Second and Fourth Medical Services (Harvard) Boston City Hospital and the Department of Medicine and the Department of Surgery, Harvard Medical School. The preparation of this paper for publication was aided by a grant from the John and Mary C. Markle Foundation.

The work described in this paper was done under a contract recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and Harvard University.

†Research fellow in medicine, Harvard Medical School, research associate in surgery and resident fellow in medicine, Thorodike Memorial Laboratory, Boston City Hospital.

‡Formerly assistant in surgery, Boston City Hospital.

§Assistant professor of surgery, Harvard Medical School, visiting surgeon, Boston City Hospital, formerly member Subcommittee on Burns, Division of Medical Sciences, National Research Council.

Shock

Treat shock or give preventive treatment for shock before dressing the burn. Intravenous electrolyte should be started first, and in all cases in which the areas given above are involved plasma should be given simultaneously.

The electrolyte should consist of the following: 10 per cent dextrose in saline solution with the three following items added per liter: sodium bicarbonate, 3.75 gm (put up in 50-cc ampules), ascorbic acid, 1 gm, and vitamin B complex, 2 ampules. The amounts to be given are shown in Table 1. If the patient is intoxicated or in delirium tremens use five times this dose of ascorbic acid and of Vitamin B complex.

The first dose of plasma should be given rapidly and the first dose of electrolyte slowly unless the patient is in actual shock. If the usual peripheral veins are not accessible or are collapsed, the fluids should be given into the femoral vein, even if the groin region is burned.

It is essential to filter the plasma through sterile gauze just before using and give it through a Murphy drip set, to observe the rate of flow. The amounts to be given are shown in Table 1.

These doses may suffice for burns of 15 to 25 per cent in adults and of 8 to 15 per cent in infants who are not in shock, but in all cases of this severity or greater the systolic blood pressure and hemoglobin must be followed. If the

TABLE 1 First Dose of Electrolyte and Plasma according to the Weight of the Patient

WEIGHT	10% DEXTROSE ELECTROLYTE IN SALINE SOLUTION	PLASMA
lb	cc	cc
150 or more	1500	750
100-149	1000	500
50-99	500	250
35-49	250	150
20-34	150	150
5-19	5 per lb	10 per lb

patient goes into shock with the blood pressure below 70 at any time, the first dose of plasma should be repeated at once or a double dose given rapidly if none has been given. The second and subsequent hemoglobin values will indicate the need for further electrolyte and plasma in the severer cases. Do not give more electrolyte and plasma except for shock unless the hemoglobin has risen ten points or has gone above 110 per cent, whichever is reached first. The second and all subsequent doses of electrolyte and plasma

*These ampules should contain in one ampule 10 mg of thiamin, 4-10 mg of riboflavin, 50-250 mg of niacinamide, 5-10 mg of pyridoxine and 5-50 mg of pantothenic acid. Among the preparations meeting these standards are Betalin Complex (Lilly), Solu B (Upjohn) and Betasynplex (Winthrop).

should be given as outlined in Table 2. Use 10 per cent dextrose in distilled water instead of saline solution during the remainder of the first twenty-four hours.

Further doses are to be given if indicated by further rises in hemoglobin. If further intravenous treatment is needed for shock after an amount of 10 per cent dextrose in distilled water has been given equal to the original dose.

TABLE 2 Subsequent Amounts of Electrolyte and Plasma to be Given for Each Point Rise in Hemoglobin or for Each Point It Is above 100 Per Cent According to the Weight of the Patient

WEIGHT	10% DEXTROSE ELECTROLYTE IN DISTILLED WATER	PLASMA
R	"	"
150 or more	50	0
100-149	35	5
50-99	20	20
35-49	15	15
20-34	10	10
5-19	0.5 per lb	0.5 per lb

of saline solution, give only plasma. Severe burns may need about 1000 cc. of plasma for each 10 per cent area of burn up to a maximum of 5000 cc. in twenty-four hours.[†]

The blood pressure determinations should be continued every half-hour for twenty-four hours, the hemoglobin every two hours until stabilized and the temperature and respiration every two hours. Children under six should have a rectal temperature every hour.

Dressing

A dressing should be applied as early as is consistent with the patient's condition. It should not be started until shock is relieved or until preventive treatment for shock has been started. The intern or resident doing the dressing must be scrubbed, gowned, capped and masked. If the dressing is difficult (25 per cent area or more or a restless or delirious patient), there must also be a scrubbed assistant. The patient should be placed on a sterile sheet and the adherent clothing removed. Blisters must not be cut or broken, and no attempt should be made to wash or clean off any dirt of any kind. A pressure dressing should be applied. Casts may be applied to extremities on direction of a visiting surgeon. The only exceptions to the above are in the cases of the face, neck, anus and genitalia, which should be covered with a thick layer of sterile vaseline and one layer of fine mesh gauze, and nothing else. Provision should be made for replacing these frequently on the ward.

Technic of Pressure Dressing

Under operating-room conditions, fine meshed gauze, dry, should be applied directly to the wound surface. Over this, sufficient Surgine* should be wrapped to make possible even compression by means of an elastic bandage. (The final dressing after compression should be about 2.5 cm. thick.) It should be emphasized that to be maximally effective the dressing should be applied as soon as permitted by the general condition of the patient, since the greatest amount of swelling occurs in the first few hours following injury. Also, since the swelling is not limited to the burned areas but occurs also in the immediately adjacent areas, these areas must be incorporated in the dressing. In burns of the extremities the dressing must extend distally to cover completely the hand and foot, even if these areas are not burned, otherwise, the venous return from these areas will be obstructed, and as the back pressure builds up, the arterial blood supply will be impaired. In certain cases where these precautions have not been taken dressings have had to be removed because of impending gangrene. Elevation of an extremity, with a properly applied dressing, may help prevent stasis and discomfort. In applying a pressure dressing the tension must be uniform, and care must be taken that no more pressure is used than required. In burns of the chest and

abdomen a pressure dressing, as such, cannot be applied without interfering with the patient's breathing, under these circumstances a firm bulky dressing without pressure is used. The initial dressing is left in place for about fourteen days. At the end of this time superficial second-degree burns are healed, while deep burns are beginning to slough.

Post-Dressing Care

Order patient sent to the ward only when well out of shock.

Order morphine in small doses.

Order pulse, respiration and blood-pressure determinations every half-hour.

Order hemoglobin determinations every two hours.

Order temperature determinations every two hours, or every hour (rectal) up to six years old.

Order report of any fall in blood pressure of 20 points or below 90 systolic, any rise in pulse of 30 points or above 120, any rise in respiration above 30 and any rise in temperature to or above 103°F or any chill or other unfavorable symptom.

Post-Dressing Shock

The treatment of this should be mainly by plasma and electrolyte, as directed above. The best sign that shock is fully relieved is a good flow of urine. Be careful of giving too much fluid, especially to very young or very old patients.

Kidney Function

Impairment of kidney function is one of the important early complications of the severely burned patient. To determine the kidney function, urine specimens are necessary, therefore, put all patients with burns of 25 per cent or greater on constant drainage for the first few days. The important etiologic factors of reduced renal function appear to be shock and hemoglobinuria. Every effort must be made to prevent the occurrence of shock or, if shock is present, to combat it vigorously and immediately. Hemoglobinuria is the result of marked hemoglobinemia, which in turn results from injury to the circulating red cells by heat at the time of burning. From analogy with hemolytic blood-transfusion reactions, prompt and continued alkalization of the urine during the period of hemoglobinemia (usually forty-eight to seventy-two hours) should be made. This can be accomplished initially by the intravenous injection of an ampule of sodium bicarbonate, in addition to that already recommended in the section on the treatment of shock. Later, additional bicarbonate should be given only if the urine fails to become or to remain alkaline.

Daily intake and output records should be kept for at least the first week in all patients with burns of 10 per cent or greater, and as much longer as is indicated in patients showing any impairment of renal function. An attempt should be made to keep the urine output between 1000 and 1500 cc. daily. Fluids during the first day should be given as outlined previously. If thereafter the oral intake is insufficient, it should be supplemented by intravenous fluids or by dialysis. No more than 1500 cc. of the supplemental fluids should be electrolyte. In cases with marked oliguria or anuria, care should be taken not to overload the patient, particularly with sodium salts. Plasma protein, nonprotein nitrogen, carbon dioxide, chloride and routine urine determinations should be frequently done.

Hyperpyrexia

Patients with burns frequently have a period of high temperature (up to 109°F) in the first two days after the burn, and not infrequently at much later dates. This is likelier if shock has been poorly treated but can occur without any shock. It is not necessarily the result of infection or of pyrogens in the intravenous fluids.

The patient with a burn does not tolerate a high temperature and will die if it remains at or above 105°F for a few hours. In most cases this fever may be brought down by energetic treatment given at once. If the fluids given have not been according to the above standards, more fluid will help, but main attention should be paid to ice-water sponge baths to all exposed skin. If less than 50 per cent of skin is exposed, it may be necessary to remove some of the dressings. Open windows, create a draft, strip off all bedclothes and make an ice-water bath in the pa-

*Surgine is the name of a composite cotton dressing material used in many hospitals for abdominal pads. Large sterilized rolls of this material are convenient for dressing large burns.

†Whole blood has recently been found to be at least as useful as plasma in the prevention of burn shock. When whole blood is used in large quantities the hematocrit and hemoglobin values are unreliable indicators of blood volume.

tient's bed and keep sponging him for half an hour or more if necessary to bring the temperature down to 102°F. Heated cradles are not to be used at any time in the care of burns. Heavy blankets are to be used only temporarily during a chill or when the room is extremely cold.

Respiratory-Tract Injury

Respiratory-tract injury is a serious complication of burns. Its presence should be suspected in any patient with flame burns of the face (even minor), particularly if he gives a story of inhaling large quantities of smoke and so forth or having lost consciousness. An aural consultation should be obtained immediately on such patients, particular attention being paid to the epiglottis and vocal cords. The room should be humidified, and a tracheotomy set should be kept at the patient's bedside. Respirations should be checked every half-hour. If any hoarseness, dyspnea or stridor occurs, the patient should be placed in an oxygen tent. If there is evidence of bronchial spasm, aminophyllin intravenously or adrenalin or ephedrin by nebulizer should be tried. If signs of laryngeal obstruction develop, immediate tracheotomy must be done. Suction through the tracheal tube should be carried out when needed. An aural consultant should be on hand to perform bronchoscopic aspiration if further obstruction develops. All personnel coming in contact with the patient should be masked.

Sedation. Restlessness may be due primarily to oxygen lack, in which case measures to increase oxygen supply as outlined above should be carried out, to pain (from surface burns), in which case Demerol, rather than morphine, should be used, or to fear and nervousness, in which case barbiturates are indicated.

Chemotherapy. Parenteral penicillin, 25,000 units intramuscularly every three hours, should be started on entry. If the urine output is good, sulfadiazine in full doses may also be given.

Local measures. If burns of the nose and pharynx are present, the patient may be made more comfortable by swabbing the nose with a bland oil and having him gargle with a soothing mixture, such as dextrose in water.

Anemia

After the second day anemia may be troublesome. Make hemoglobin determinations daily until stabilized, and then weekly until discharged. Give whole-blood or red-blood cells in sufficient amounts to keep the hemoglobin at 90 per cent. Any level below 80 per cent should be corrected at once.

Nutrition

Loss of weight, often marked, has long been recognized as a serious complication in severely burned patients.

The estimation of the status of a burn patient with regard to the presence or degree of nutritional deficiency is not simple. The factors necessary for a critical evaluation are the optimum weight of the patient, the observed weight of the patient, the plasma protein level, the plasma albumin level, the plasma volume, the nitrogen intake and the nitrogen output. Actually, main reliance in clinical work has to be placed on a nutritional history, on the patient's weight and on serum protein determinations.

The weights of these patients may be secured at each dressing change by putting the patient, covered with a sterile sheet but with the dressings removed, on a weighed stretcher, each end of which is placed on a scale. Slight changes of weight are often the first indication that the patient's nutritional condition is getting better or worse.

The food provided must be an adequate metabolic mixture containing, in addition to adequate amounts of protein, sufficient calories, fat, carbohydrate, minerals, water and accessory food substances. As seen in Table 3, the minimum essential needs for protein, calories and vitamins are as great as or greater than the need for these items in an illness of any kind. This table is to be followed for adults and for children weighing 50 pounds and over. Reduce by 25 per cent from thirty to forty-nine pounds, and by 50 per cent from fifteen to twenty-nine pounds. Under fifteen pounds give 125 per cent, 150 per cent, 200 per cent and 300 per cent, respectively, of normal pro-

teins and calories for 1-4, 5-9, 10-19 and 20+ per cent burns. Give 25 per cent of vitamins indicated for the area in above table to these infants.

Additional vitamins from liver and yeast are helpful. Severe cases should be given up to 30 gm of yeast a day. Liver may be given in the form of liver extract.

Whenever possible, protein losses or deficiencies should be corrected by oral feeding. It is not enough for the surgeon to order a high-protein, high-calorie, high-vitamin diet. If such a diet is ordered, the patient may fail to benefit from the order for any one of the following reasons. The diet presented to the patient is not as specified. The

TABLE 3 *A Minimum Food Needed Daily by Patients with Burns, according to Total Area Unhealed*

BURN AREA	PROTEIN	CALORIES	ASCORBIC ACID	THIAMIN	RIBO-FLAVIN	NICOTIN AMIDE
%	gm		gm	mg	mg	mg
20	300-400	5000	2.0	50	50	500
10-19	200	3500	1.0	25	25	200
5-9	125	3000	0.5	15	15	100
1-4	90	2500	0.5	10	10	50

diet presented is not eaten in whole or in part because it lacks palatability, there is lack of appetite, and there is a lack of nurses to encourage eating. Food eaten may be partly or wholly lost because of diarrhea or vomiting.

These difficulties have been frequently encountered in caring for patients with burns during the last two years. The fact that the first item is mentioned may be a surprise. What especially happens in these days with the shortage of nurses is that there are frequent times when supplementary feedings are not brought to the patient because the nurse has other duties to perform that she thinks are more important or more urgent. This is particularly likely to happen at night.

The three items listed under the second item are interrelated. It is a common experience to find that a sick patient has no appetite. If, however, special attention is paid to the likes and dislikes of the patient and special or other nurses are available to encourage eating and to offer meals when the patient desires them instead of only at stated routine times, many such patients will eat a surprisingly large amount of food.

The two items under the third item are also related to each other. Forcing the diet on a sick patient does not always result in a net gain. Nausea, vomiting, distention and diarrhea, singly or together, are limiting factors. In general, the sicker the patient is the less fat is tolerated and the larger the proportion of protein should be. It has been found that at least 25 per cent of the calories in the diet should come from protein and not over 15 per cent from fat if any of these intestinal symptoms have recently occurred. It is well to take a number of days to increase the food intake, since sudden increases are likelier to be followed by gastrointestinal symptoms, which can usually be avoided by more cautious increases. If this diet is not tolerated, protein in the form of a digest should be tried and will frequently be well tolerated. The available digests are not particularly palatable and should generally be given by intubation.

Intubation feeding is important and may be used to increase greatly the intake of food. Medium-caliber nasal stomach tubes are used and left in all the time or for many hours a day. If left in continuously, the tube should be removed every third or fourth day for cleaning. About 200 cc of fluid may be given at a time, spaced between meals and at night, but there is a wide variation in the amount and frequency of supplementary tube feedings that different patients can take. It is well to start with a mixture of half skim milk and half water or one of protein hydrolysate and carbohydrates. Instead of supplying the mixture in intermittent doses, a drip apparatus may be used that can, after a short period of training, be regulated by some patients themselves. If 125 to 150 gm of protein and 2000 to 2500 calories are given by intubation in addition to an average house diet, the patient should receive a total of about 200 gm of protein and over 4000 calories. Usually, however, the patients who are

given forced supplementary feeding will not take the whole of their house diet in addition

In certain patients needing only moderately high diets and in nearly all those needing 300 gm of protein or sugar, it may be impossible to furnish the required foodstuffs by the oral or gavage route. In these cases supplemental intravenous feedings are indicated. Intravenous feedings are also indicated in cases of disturbed gastrointestinal function, either primary or secondary to nutritional disturbance. In the latter cases there may be surprising improvement in gastrointestinal function after intravenous alimentation.

Parenteral feeding should be continued as a supplement until oral feeding, with or without gavage, has been established at a sufficient level not only to maintain the patient in nutritional equilibrium but also to restore at a rapid rate all tissues that have been depleted. Up to 225 gm of protein equivalent have been given in twenty-four hours in the form of an acid hydrolysate of casein (Parenamine) or an enzymatic hydrolysate of casein and pancreas (Amigen). The suggestion of Butler and Talbot² for increasing the value of intravenous protein hydrolysates by adding dextrose has been successfully followed. By adding 300 cc of 50 per cent dextrose to 1000 cc of Amigen, there is obtained 1500 cc of a solution composed of 4 per cent hydrolysate and 15 per cent dextrose, which represents 50 gm of protein and 1000 calories. This quantity can be given into a large vein with a 20-gauge to 21-gauge needle in four hours, without much danger of thrombosis of the vein and can be repeated three times a day. The speed of administration is limited by the amount of dextrose present, the ratio of dextrose administration not exceeding 0.8 gm per kilogram of body weight per hour. Administration at a faster rate produces glycosuria and excessive diuresis. Nausea may be caused if the enzymatic hydrolysate is introduced too rapidly, and thrombosis of the vein used for the injection may occur with the acid hydrolysate.

In late stages of severe burns, testosterone propionate should be given in doses of 25 mg intramuscularly every other day to increase the positive nitrogen balance by reducing the loss of nitrogen in the urine.

Subsequent Dressings and Grafts

These should be done infrequently, about ten to fourteen days apart, and in the operating room under strict asepsis.

The dressings should be large, bulky and firm. Until some antiseptic of value is found, no ointments and no chemicals should be used except on the face, neck, genitalia and anus. The ointment dressings on these areas alone should be done whenever necessary, and therefore frequently, on the ward. Skin grafts should be placed on all deep burns at the earliest possible time. Frequent dressings and surface antiseptics are not needed and should not be used before grafting. The dressings outlined above are the best possible preparation for grafting. If hemolytic streptococci are found, intramuscular penicillin should be used before and after grafting in doses of 20,000 units every two hours. In the absence of the streptococcus penicillin is not necessary. Dermatome grafts should be employed whenever possible. When general anesthesia is needed for grafting or for dressings the anesthetic of choice is cyclopropane.

NURSING CARE

Even in spite of carrying out every item in this outline, the fact remains that a patient with a deep burn of 5 per cent or more can be saved only if special nursing care is given. This is not at present provided on the wards of many hospitals unless special nurses are available. Any patient with an unhealed deep burn of 20 per cent or more needs three nurses a day, with one of 10 to 19 per cent, two periods of special nursing a day are needed, and with one of 5 to 9 per cent, one period of special nursing a day is needed.

A full discussion of the present status of the treatment of burns has been published and explains the reasons for the directions given here.³

EFFERVESCENT MIXTURES AS ADJUVANTS TO THE RAPID ABSORPTION OF INGESTED DRUGS*

GIORGIO LOLLI, M D,† AND RUTH SMITH, B A ‡

NEW HAVEN, CONNECTICUT

ALTHOUGH there are many and obvious advantages to the oral administration of drugs, there are certain equally obvious disadvantages. Of these the most prominent are the uncertain and variable rate of absorption and gastric irritation. It is probable that when irritation occurs, its intensity varies with the duration of the contact of the drug with the gastric mucosa, and that it is least when emptying of the stomach is rapid. Since few drugs are absorbed directly from the stomach, the rate of emptying affects the speed of therapeutic response, and for drugs whose action depends on concentration developed in the blood,—for example, salicylates and sulfonamides,—the rate of emptying affects the extent of the therapeutic effect derived from a single dose. Any adjuvant procedure that prevents delay in the emptying of the stomach and obviates variations in the rate of emptying overcomes, at least partially, some of the handicaps of oral therapy. This fact has special importance for drugs which in themselves may delay emptying, as may large doses of acetylsalicylic acid, as has been shown by Schnedorf, Bradley and Ivy.¹

The study presented here extends the investigations of these authors on the effects of salicylates on the rate of emptying. It further deals with the relation between the rate of emptying and the concentration of drugs developed in the blood and with the influence of acids, alkalies, carbon dioxide and effervescent mixtures on the rate of emptying of the stomach and speed of absorption.

INFLUENCE OF SALICYLATES ON RATE OF GASTRIC EMPTYING

Schnedorf, Bradley and Ivy have reported delay in emptying of the stomach after oral doses of 1 and 2 gm of acetylsalicylic acid. To determine whether this delay was due in part to the systemic effects of absorbed salicylate, the emptying time was determined in a series of rats to which the salicylate was administered intravenously. The rate of emptying was evaluated from the percentage retention at two hours of a test meal of 25 per cent solution of dextrose, to the amount of 2.5 gm of dextrose per kilogram of body weight. Thirty-nine rats were used—30 as experimental animals and 9 as controls, which received injections of saline instead of the salicylate solution. Thirty minutes after the injection of sodium salicylate or saline solution the test meal was

given. Two hours later the animals were anesthetized with sodium amytal, the abdomen was opened, and the stomach was quickly tied off and removed. The amount of unabsorbed dextrose in the stomach contents was determined by the method of Shaffer and Somogyi.² The findings are presented in Table 1.

TABLE 1 *Influence of Intravenous Administration of Salicylate on Rate of Emptying of Stomach in Rats*

AMOUNT OF SALICYLATE gm/kg	NO OF ANIMALS	DEXTROSE RECOVERED FROM STOMACH	
		EXTREMES	AVERAGE
None	9	0-5	2
0.05	8	1-5	2
0.10	8	2-39	14
0.25	6	31-78	43
0.50	8	55-78	66

The gastric emptying was not influenced by small doses of salicylate but was markedly delayed by the systemic action of large doses. For doses of 0.05 gm per kilogram, there was no appreciable delay in emptying time and the retention at two hours averaged only 2 per cent, but with doses of 0.5 gm, 66 per cent of the test meal was still in the stomach at two hours.

The larger doses and correspondingly high concentrations of salicylate in the blood have significance in the therapy of rheumatic fever but none for the use of salicylates for analgesia. To determine the possible effects on gastric emptying of the local action of salicylates on the gastric mucosa in the presence of low concentrations in the blood, as in ordinary analgesic doses, a series of determinations was made on 3 normal human subjects. They were given 0.6 gm of acetylsalicylic acid and 100 cc of water and, in control experiments, water but no salicylate. The rate of emptying was determined by fluoroscopic examination at intervals of fifteen minutes, using the test meal and technic developed by Van Lière and Sleeth.³ The average times were obtained from a number of observations made at intervals of several days. For Subject 1 the average, when water alone was given, was two hours and fifteen minutes and after acetylsalicylic acid, two hours, for Subject 2 the corresponding values were one hour and forty-five minutes and two hours, for Subject 3, they were two hours and one hour and forty-five minutes. It appears that this salicylate has, in ordinary doses given for analgesia, no delaying action from local or systemic effects on the rate of gastric emptying.

INFLUENCE OF ACIDS, ALKALIES AND EFFERVESCENT MIXTURES ON RATE OF GASTRIC EMPTYING

A comprehensive review of the influence of acids and alkalies on the rate of emptying of the stomach will be found in the writings of Van Lière and Sleeth.⁴ In spite of conflicting results the well substantiated findings are as follows. Strong acids inhibit gastric motility, whereas weak acids have an undetermined effect, and moderate amounts of sodium bicarbonate hasten and large amounts slow the emptying time. There is no full agreement among investigators concerning the mechanism involved. Van Lière and Sleeth suggest three hypotheses: an effect on the action of the pylorus, an effect on the secretory activity of the stomach followed by changes in motility and a direct effect on gastric motility. Objections can be raised against all three of these explanations.

In the experiment reported herein 3 normal human subjects were used. The rate of gastric emptying after a test meal, as described above, was determined at intervals of several days. In a series of control determinations made with water administered ten minutes after the test meal, it was found that the rate of emptying for each subject was fairly uniform. The water was replaced on separate occasions by an equal volume of fluid containing 1.5 gm of tartaric acid, 2.0 gm of sodium bicarbonate or an effervescent mixture of 1.5 gm of tartaric acid and 2.0 gm of sodium bicarbonate. Three determinations were made on each subject for each of the materials administered. The findings are given in Table 2. As seen from this table

the rate of emptying was not appreciably influenced by tartaric acid but was markedly shortened by sodium bicarbonate and by an effervescent mixture of the two substances. These findings will be discussed later.

To avoid continual fluoroscopic procedures and to check the validity of the data obtained by fluoroscopy, the rate of gastric emptying was determined by direct measurement. By means of a Levin tube the stomach contents were withdrawn at intervals and, after the volume had been determined, re-

injected into the stomach. Each subject was trained to pass the tube without assistance, after a few days of practice nausea and apprehension which might affect gastric motility, disappeared. A bouillon test meal was used.

The subjects received their last meal at dinner the day previous to each experiment and no fluid after midnight. At 9 a.m. the tube was passed and the small amount of gastric juice present in the stomach was withdrawn for preliminary determination of the hydrogen-ion concentration. Bouillon was then swallowed and immediately thereafter 100 cc of the solution under study. The tube was left in place for the duration of the experiment. At intervals of fifteen minutes the stomach contents were withdrawn as completely as possible and measured. A few cubic centimeters was retained for measurement of the reaction and the remainder was returned to the stomach.

That repeated withdrawal and return had no appreciable influence on the rate of gastric emptying was shown by comparative determinations in which the stomach contents, on one occasion, were removed and returned as described and on another were allowed to remain for an hour before removal. The values obtained are shown in Table 3.

At intervals of several days two additional determinations were made on the two subjects, using 100 cc of bouillon and 100 cc of water. The findings

TABLE 3 *Volume of Stomach Contents with Single and Repeated Withdrawals*

are given as the first four values in Table 4. As seen, the residuum at one hour was substantially the same as in the determinations recorded in Table 3.

Again at intervals determinations were made after the subjects were given the following: 100 cc of bouillon and 100 cc of effervescent mixture containing sodium bicarbonate (4 gm) and tartaric acid (3 gm), but with the mixture boiled to remove all free carbon dioxide and subsequently cooled, 100 cc of bouillon and 100 cc of effervescent mixture, not boiled but with active effervescence, and 100 cc of bouillon and 100 cc of carbonated water. The findings are given in Table 4. As seen, the effervescent mixture, unboiled, hastened the emptying of the stomach with a residuum averaging 20 cc at sixty minutes, as compared to 100 cc for the control experiments. A comparable hastening effect resulted when carbonated water was used instead of the effervescent mixture. A moderate hastening

effect resulted when the effervescent mixture was boiled prior to administration. Under the conditions of these experiments there appeared to be no correlation between the hydrogen-ion concentration of the gastric juice and the extent of gastric emptying.

Tartaric acid was used in this experiment rather than citric acid, which is often employed in effervescent mixtures, to avoid any effects from possible systemic alkalization due to the oxidation of the citric acid. Tartaric acid in doses of 15 gm has no effect on gastric emptying.

The fact that carbonated water hastens gastric emptying confirms the work of Carnot and Koskowski,⁵ Kussmaul,⁶ Jaworski⁷ and Binet and Lebon.⁸ In addition, it casts some light on the pos-

small and large doses of sodium bicarbonate. In the presence of a normal gastric acidity, a small dose of sodium bicarbonate hastened the emptying of the stomach. In subjects with a hyperchlorhydric response to the test meal, the same dose of sodium bicarbonate caused an even greater hastening in gastric emptying. In those with an achlorhydric response, it had no effect on the rate of emptying. The interpretations made of these findings, in the light of the work presented here, are as follows. In the presence of a normal amount of hydrochloric acid in the gastric juice, the ingestion of moderate amounts of sodium bicarbonate causes liberation of carbon dioxide, with consequent hastening of gastric emptying. In the absence of hydrochloric acid, carbon dioxide cannot be liberated and there is con-

sible mechanisms of effervescent mixtures in general. In the experiments reported herein the effect of the effervescent mixture on gastric emptying did not disappear completely after boiling to remove the carbon dioxide from the effervescent mixture. The relative amounts of sodium bicarbonate and tartaric acid in the mixture used were such as to leave an excess of about 1 gm of bicarbonate after boiling. Such an amount does not seem sufficient to account for the effect observed, which may have been due in part to sodium tartrate. From experiments, to be described later, there is evidence that sodium tartrate hastens gastric emptying. Van Lière and Sleeth⁴ have shown that disodium phosphate has this effect.

The greater effect of the unboiled effervescent mixture as compared to the boiled is undoubtedly connected with the liberation of carbon dioxide, which plays a predominant role in shortening gastric emptying following administration of effervescent mixtures. Sodium bicarbonate in normal healthy subjects exerts an action substantially the same as that of the effervescent mixture, and it is our opinion that it acts mainly through the liberation of carbon dioxide by reaction with the hydrochloric acid of the gastric juice.

Shay and Gershon-Cohen⁹ investigated the rate of gastric emptying following administration of

sequently no hastening of gastric emptying. When large amounts of bicarbonate are given only a part reacts with hydrochloric acid in the normal subjects, and it is possible that the large amount of residual alkali counteracts the effects of the carbon dioxide. In hyperchlorhydric subjects, as shown by Shay and Gershon-Cohen, an increased rate of emptying occurs even when large amounts of bicarbonate are given, a result that may possibly be attributed to the greater evolution of carbon dioxide and lesser residual alkali.

If this interpretation of the data of Shay and Gershon-Cohen is correct, the role played by carbon dioxide in hastening gastric emptying seems significant not only when carbonated water is administered but also when sodium bicarbonate and effervescent mixture are given. It should be emphasized that when bicarbonate alone is used in a normal subject, the need is for moderate rather than large doses, and that the effectiveness in hastening gastric motility is, in large part, conditioned on the presence of hydrochloric acid in the stomach.

INFLUENCE OF GASTRIC EMPTYING TIME ON ABSORPTION OF DRUGS

The concentration of sulfathiazole in the blood was determined in 2 subjects at intervals after taking 0.25, 1.0 and 3.0 gm of the drug, with and with-

out an effervescent mixture consisting of sodium bicarbonate and tartaric acid. The findings are shown in Table 5. The use of the effervescent mixture favors a high concentration in the blood in the early phase of absorption, which is especially marked with the small and moderate doses.

Rapid absorption with an earlier rise of the concentration of the drug in the blood is perhaps of less specific therapeutic importance with a drug such as sulfathiazole, with which prolonged maintenance

The most striking feature is the higher concentration of salicylate in the blood up to two hours for doses of 0.6 gm and to four hours for doses of 1.6 gm when given with various adjuvants. The effervescent mixture was the most effective in increasing the concentration. The increase in concentration signifies a definite benefit in rapid therapeutic action.

These experiments appear to indicate that small amounts of markedly alkaline salts hasten the

of concentration is desired, than with acetylsalicylic acid used as an analgesic, with rapid action as a desideratum. It should be borne in mind, however, that the more rapid emptying correspondingly limits the possible gastric irritation from the drug.

Similar experiments carried out with acetylsalicylic acid were intended not only to determine

emptying time of the stomach irrespective of the production of carbon dioxide, that carbon dioxide alone hastens gastric emptying, and that in interpreting the action of an effervescent mixture the following factors enter into consideration: the carbon dioxide produced, the weak alkaline salts formed from the reaction inducing the effervescence and

the influence of the effervescent mixture on emptying of the stomach but also to clarify the part played by the carbon dioxide liberated and by the salts formed from the effervescent mixture. Acetylsalicylic acid in doses of 0.6 and 1.6 gm was given to 2 fasting subjects with an effervescent mixture of tartaric acid (3 gm) and sodium bicarbonate (4 gm) with sodium citrate (4 gm), with sodium tartrate (4 gm) and with carbonated water (150 cc). The findings are given in Table 6.

the alkalinity that may occur from an excess of bicarbonate.

CONCLUSIONS

Attempts at hastening the rate of gastric emptying seem warranted when a quick effect of a drug orally administered is required with minimum irritation of the stomach. Such attempts seem further justified by the possibility that some drugs delay gastric emptying when given in large amounts.

Evaluation of the rate of gastric emptying by means of fluoroscopic examination, gastric intubation and determinations of blood concentrations of test drugs indicates that effervescent mixtures decrease the emptying time of the stomach.

The effect attendant on the administration of an effervescent mixture seems to be due in part to the presence of weak alkaline salts and in part to the production of carbon dioxide.

MEDICAL PROGRESS

NEUROLOGY

H. HOUSTON MERRITT, M.D.*

NEW YORK CITY

THE significant publications in the field of neurology in 1945 included a number of studies on the physiology of the nervous system, further reports on the use of antibiotics in the infections of the nervous system, including syphilis and tuberculous meningitis, the introduction of a new drug in the treatment of petit-mal epilepsy and articles on various miscellaneous subjects.

PHYSIOLOGY

Two studies on the physiology of the pyramidal tract have been contributed by Lassek.^{1,2} In the first he correlated the occurrence of the Babinski reflex with the other evidence of damage to the corticospinal tract. The material used in this study comprised 1600 case reports collected from the literature in which the Babinski sign was exhibited. The Babinski reflex was present bilaterally in 85 per cent of the 200 cases that showed various degrees of suppression of the somatic nervous activity, such as that occurring in unconscious states. All degrees of motor activity from normal to complete paralysis were found. The signs and symptoms that accompanied the Babinski sign, in the order of frequency, were somatic motor deficit, hyperactive patellar reflex, absence of abdominal reflex, spasticity, ankle clonus, hypoactive knee jerk, absence of cremasteric reflex, flaccidity and patellar clonus.

In the second study, Lassek attempted to determine the frequency of changes in the axones in the pyramids in patients who had evidence of cerebrovascular lesions during life. Sections of the medulla

of 166 such patients were stained by the Davenport method. There was complete destruction of the axones in the pyramids in only 7, and partial damage in 36. No loss of fibers in the pyramids could be demonstrated in 63 cases, although many of these patients had a hemiplegia during life. Lassek concludes that hemiparesis or hemiplegia, caused by chronic cerebral vascular lesions, may occur with little or no destruction of the fibers in the pyramid of the medulla.

Studies in disturbances of the sleep mechanism were made by Davison and Demuth.^{3,4} In 9 patients pathologic sleep was associated with lesions confined to the cortex. Increased intracranial pressure was present in only 4 of these cases, and compression of the hypothalamus was excluded in 7. From their histologic study of the brains of these 9 cases, the authors conclude that some fibers for the cortical control of sleep originate in the cerebral cortex, especially the hippocampal, cingular, frontal and temporal convolutions. In 25 patients with pathologic sleep there was involvement of the corticodiencephalic structures. The hypothalamus was invaded or compressed in 16 cases, and the basal ganglia were involved in 16. The authors state that fibers for the control of sleep, which originate in the cortex, reach the hypothalamus by way of the median forebrain bundle, the fornix and the inferior thalamic peduncle.

The effect on the nerve-action potential of various choline esterase inhibitors was studied by Bullock, Nachmansohn and Rothenberg.⁵ They have found that strychnine, eserine and cocaine reversibly depress the action potential of the giant axone of

*Professor of clinical neurology, College of Physicians and Surgeons, Columbia University, chief of Division of Neuropsychiatry, Montefiore Hospital.

the squid Prostigmine, despite its *in vitro* action on choline esterase, does not affect the action potential because it is a quaternary ammonium and cannot penetrate a lipid membrane. The authors consider their findings to be consistent with the theory that acetylcholine is the depolarizing agent released during the passage of the impulse and that the physiologic role of choline esterase should be the rapid removal of the ester, inhibition of the enzyme should result in enduring depolarization and therefore abolition of conductivity.

The sympathetic dermatomes in the lumbar and sacral regions are outlined by Richter and Woodruff⁶ in 75 patients who had sympathectomies in this region. With the electrical skin-resistance method, the area of increased skin resistance followed a definite segmental pattern that corresponded closely to the sensory and vasomotor dermatomes determined by Foerster.

A new method of determining cerebral blood flow in man is described by Kety and Schmidt.⁷ The method is based on the principle that the rate at which the cerebral venous blood content of an inert gas (nitrous oxide) approaches the arterial blood content depends on the volume of blood flowing through the brain. Comparison of the results with the use of this method with those obtained by the direct measurement of flow in monkeys showed that the gaseous method was quite accurate.

The effect of the administration of phenobarbital or dilantin on the recovery of motor function following ablation of the fourth and sixth cortical areas in monkeys was studied by Watson and Kennard.⁸ Phenobarbital in nonsedative doses retarded the rate of recovery. Dilantin alone had no effect on the rate or recovery of motor function, but dilantin when administered together with doryl inhibited or prevented the enhanced recovery rate that occurs when doryl is given alone.

Richter⁹ reports that degenerative changes can be produced in the basal ganglia of monkeys when the animals are chronically poisoned by exposure to carbon disulfide vapor for many months. The pathologic changes consist of extensive necrotic lesions in the globus pallidus and the substantia nigra. The animals present many of the clinical signs often seen in disease of the basal ganglia in man, but the parkinsonian type of tremor has not been observed.

Bender¹⁰ states that although polyopia and monocular diplopia usually are hysterical symptoms, they may occur on an organic basis. He emphasizes the fact that lesions in the occipital lobe or central visual pathways, as well as lesions in the media of the eye, can be followed by polyopia or monocular diplopia.

Curare was used by James and Braden¹¹ in the treatment of 12 paraplegic patients, injured in war, who suffered with annoying and distracting flexor withdrawal reflexes of the lower extremities. The

use of this drug resulted in a decrease in the frequency and severity of the reflexes, with resulting general improvement.

INFECTIONS

A case of tuberculous meningitis in a one-year-old infant treated with streptomycin is reported by Cooke, Dunphy and Blake.¹² The diagnosis was confirmed by cerebrospinal-fluid abnormalities and by guinea-pig inoculation. The streptomycin was administered intramuscularly and intrathecally. The baby had survived for two hundred and thirty-four days since the start of the treatment. The meningitis was apparently entirely cured, but there were residuals indicating severe damage to the nervous system.

Twenty-eight consecutive cases of influenzal meningitis were treated by Smith, Wilson and Hodes.¹³ The incidence of influenzal meningitis in infancy follows a curve similar to that of pneumococcal meningitis, that is, most cases occur between the ages of three and nine months. Early diagnosis and intensive therapy, with the use both of sulfonamides and of type-specific antibody, reduced the mortality to 7 per cent, which is comparable to that of meningococcal meningitis. The incidence of serum reactions was high but did not militate against its use.

The neurologic complications of meningococcal meningitis formed the subject of reports by Farmer¹⁴ and by Degen.¹⁵ Focal neurologic signs were present in 26 of the 300 patients reported by Farmer. There were 9 cases with sixth-nerve paralysis, 9 with seventh-nerve paralysis, 5 with eighth-nerve paralysis and 3 with transient focal cerebral complications — convulsions, hemiplegia and aphasia. The sixth-nerve paralysis, which was most often unilateral, developed early in the course of the disease, while the cerebrospinal fluid was purulent, and complete recovery usually occurred within a few weeks. The seventh-nerve paralysis, either unilateral or bilateral, was a late complication, developing five to fourteen days after the onset and at a time when the cerebrospinal fluid was relatively cell free. Recovery from the facial paralysis was usually complete within a few months. Eighth-nerve paralysis occurred more frequently in children than in adults. Both eighth nerves were usually involved, and the hearing loss was permanent. A follow-up study of 986 patients with cerebrospinal meningitis was made by Degen.¹⁵ Sequelae of the meningitis were found in 387 patients, 91 of whom were incapacitated. The sequelae included the following: emotional instability, in 109 patients; headache, in 170; backache, in 46; inability to concentrate and poor memory, in 8; total deafness, in 27; impaired vision, in 22; disturbances of vision, in 7; strabismus, in 9; aphasia, in 2, both patients being over fifty years of age; poor balance, in 20; and dizziness, in 13.

The results of the use of penicillin in the treatment of neurosyphilis are reported from several clinics. Gammon and his associates¹⁶ summarize the changes that occurred in the cerebrospinal fluid of 89 patients treated with 1,200,000 to 4,000,000 units of penicillin. The cell count and protein content of the cerebrospinal fluid was reduced to normal in all but 6 patients. The authors conclude that large doses of penicillin, especially when repeated, give the best results.

O'Leary and his co-workers¹⁷ report their results with the use of penicillin in 100 patients with various types of neurosyphilis. The dosages varied from 1,200,000 to 8,000,000 units, and the routes of administration included the intramuscular, intravenous and intraspinal. The clinical and serologic response in patients with meningeal neurosyphilis was excellent, whereas patients with dementia paralytica were improved only slightly, if at all. The combination of penicillin and fever therapy did not improve the results noted from the fever treatment alone. Good results were obtained in reversing the cerebrospinal fluid abnormalities in patients with asymptomatic neurosyphilis who received 1,200,000 units of penicillin in one week in association with either three spinal drainages or intraspinal treatments with penicillin. The authors conclude that the administration of penicillin by the intravenous, intramuscular or intraspinal route is not capable of controlling the parenchymatous forms of neurosyphilis.

Rose¹⁸ reports the results from the use of penicillin in combination with fever therapy in 140 cases of symptomatic neurosyphilis. The treatment consisted of the intramuscular injection of 3,000,000 units of penicillin combined with a short course of fever therapy, half the amount usually prescribed. The results in 36 patients with reasonably early dementia paralytica were improvement in 24, no change in 11 and worsening in 1. There was improvement in only 1 of the 13 cases of long-standing dementia paralytica. No dramatic change was noted in the course of the patients with tabes dorsalis. The progress of the visual loss was arrested in 5 of 6 cases of optic atrophy. The effect of penicillin on the cerebrospinal-fluid abnormalities compared favorably with that of other forms of antisiphilic treatment.

The hazards of administration of penicillin and other substances intrathecally is the subject of three articles. Siegal¹⁹ reports the case of a sixty-six-year-old woman with Type 14 pneumococcus meningitis who was treated with sulfadiazine by mouth and with penicillin by the intravenous and intraspinal routes. The patient recovered from the meningitis but developed a flaccid paralysis, complete sensory loss below the level of the tenth thoracic segment and loss of sphincter control. The neurologic residuals were permanent. A case of meningitis with headache, stiff neck and fever fol-

lowing the intrathecal injection of Pantopaque is reported by Tarlov.²⁰ Biopsy of the meninges confirmed the diagnosis of meningitis. Three cases of spinal arachnoiditis and paralysis following spinal anesthesia are reported by Kennedy, Somberg and Goldberg.²¹

CONVULSIVE DISORDERS

Experiments were made by Forster²² on the effect of acetylcholine on the electrical activity of the cortex of cats. He reported that the electrical discharges thus produced were similar to seizure discharges and were correlated with the muscular components of seizures that followed the application of the acetylcholine to the cortex.

Several new drugs have been tested as anti-convulsants in human beings. Clein²³ reports beneficial effects in grand-mal epilepsy and to a less extent in petit-mal epilepsy by the administration of Hydantal (3-methyl, 5-phenylethyl hydantoin) and phenobarbital. On the basis of 10 cases the author states that Hydantal has all the advantages of previous hydantoin derivatives but is without their toxic effects.

The anticonvulsant activity of sulfoxides and sulfones was tested in animals by Merritt, Putnam and Bywater.²⁴ Several of the phenyl derivatives of these compounds were found to have anti-convulsive activity in animals. One of these, ethyl phenyl sulfone, was given a clinical trial in patients with epilepsy. It was found that this drug had definite anticonvulsive activity in such patients, but this activity was not sufficiently greater than that of phenobarbital or phenytoin sodium to justify its recommendation for general use.

The use of Tridione (3,5,5-trimethylloxazolidine-2,4-dione) in the treatment of epilepsy was reported by Thorne,²⁵ Lennox²⁶ and DeJong.²⁷ Thorne administered Tridione to 11 patients with grand-mal seizures and compared the results with that obtained with previous forms of treatment. There was improvement in 3 patients, no change in the frequency of seizures in 6 and death from extraneous causes during treatment in 2. Lennox describes the clinical and electroencephalographic characteristics of petit-mal epilepsy and reports on the effects of administration of Tridione to 50 patients with petit-mal seizures. The drug was effective in controlling the seizures in 28 per cent and reduced their frequency in 52 per cent. In 10 patients who had occasional or frequent grand-mal seizures in addition to the petit-mal attacks, the administration of Tridione did not control the former. The principal side effect of treatment was photophobia, which affected adults and older children more frequently than it did younger children. DeJong administered Tridione in combination with Phenytoin Sodium, phenobarbital and bromides to 6 patients who were subject to minor epileptic seizures classified under the term "psychomotor attacks." Some of these patients also had

grand-mal and petit-mal seizures DeJong reported that Tridione in dosages of 0.32 gm three times daily was effective in controlling the psychomotor attacks in cases in which the other anticonvulsive drugs had failed

HEADACHE

The observation that distended temporal arteries are sometimes palpable in patients with migraine and that as the attack continues these arteries become more rigid and pipelike and less compressible led Torda and Wolff²⁸ to try to reproduce these findings in cats. The arteries of the ears of 6 cats were studied after infusion for two hours with a solution containing a vasodilator, acetylcholine being used. Measurements demonstrated thickening of the arterial walls of the infused ears. It was also observed that a vasoconstrictor, ergotamine tartrate, was less effective in constricting arteries with thickened walls than in constricting those with normal walls. It was suggested that with prolonged dilatation during attacks of migraine the cranial arteries may undergo similar changes, thus explaining the rigid pipelike texture of the arteries and the decreased ability of ergotamine tartrate to reduce promptly the intensity of the headache.

Friedman, Brenner and Merritt²⁹ injected 0.1 mg of histamine base intravenously in patients subject to recurring attacks of headache and in controls. The headache that usually follows such an injection appeared to be closely dependent on a secondary rise in blood pressure that follows the initial fall, as shown by the absence of such a rise in patients in whom headache failed to develop, the temporary disappearance or amelioration of the headache caused by compression of the carotid artery and the temporary disappearance of the headache following a secondary injection of histamine. Support or the lack of it afforded the walls of the intracranial arteries by the cerebrospinal-fluid pressure seems to play a small part in the production of such headaches, as shown by the absence of improvement during jugular compression or, in most cases, during inhalation of an oxygen and carbon dioxide mixture. The essential mechanism of experimentally produced histamine headache seems to be the mechanical stimulation of pain-sensitive structures in or near the walls of intracranial arteries, caused by distention of the relaxed walls by blood driven in under increasing pressure.

CEREBROVASCULAR LESIONS

In a comprehensive review of vascular disease of the nervous system, Aring³⁰ correlates the various manifestations of cerebrovascular disease with the known facts regarding the physiology of cerebral circulation. He emphasizes the fact that the main factors that control the cerebral circulation are extracerebral. Such occurrences as sudden reduction in systemic blood pressure may be followed by lesions

in a brain that has pre-existing pathologic changes in its vessels. Similarly, changes in the permeability of blood vessels in patients with disease of the cerebral vessels may be followed by a cerebrovascular lesion.

Wolf, Goodell and Wolff³¹ made a follow-up study of patients with subarachnoid hemorrhage. They found that the mortality rate from the first episode of bleeding was 29 per cent. Fourteen per cent of the patients died from recurrence of the bleeding within two to four weeks, and an additional 5 per cent were dead within one year. On the basis of these findings, the authors recommend that an arteriogram be performed on all patients who come under observation during the first four weeks after a subarachnoid hemorrhage. If an aneurysm is visualized, a craniotomy should be performed and the aneurysm treated surgically. Patients who have had their hemorrhage more than four weeks previously and who have localizing signs of an intracranial mass should receive arteriography and craniotomy if suitable indications exist.

THE CENTRAL NERVOUS SYSTEM IN VARIOUS SYSTEMIC DISEASES

Knutson and Baker³² studied in detail the tissues in 12 patients who had died of uremia. They state that these cases may manifest symptoms covering the entire field of neuropsychiatry. Most frequently these are convulsions and coma, but in isolated cases unusual syndromes, such as monoplegia, hemiplegia, aphasia and all varieties of mental symptoms, may be present. There were widespread changes in the nervous system involving both the nerve cells and the parenchymal elements. If the disease ran an acute course, the predominant alteration occurred in the cortical neurons. In the chronic cases, the striking changes were parenchymal rather than neuronal, consisting of focal and perivascular demyelination and necrosis, although neuronal changes were also present.

Ferraro, Arieti and English³³ examined the brains of 5 patients with pernicious anemia in whom the manifestations of this disease appeared to have developed in the course of a psychosis. One case of pernicious anemia without psychosis and 1 that developed a psychotic syndrome in the course of an established pernicious anemia were also reported. The psychosis was of the paranoid schizophrenic type, with ideas of persecution and grandeur, and a withdrawal type of behavior. The pathologic picture, which occurred in all cases including the one without neuropsychiatric symptoms, consisted of vascular changes, — mild endarteritis and proliferation, — ischemic cell changes, clumping of glial cells about vessels and the presence of areas of demyelination that tended to coalesce. In 2 cases the vascular changes typical of Wernicke's encephalopathy were found. These changes were most intense in the regions usually involved in that disease.

Since no mental symptoms were observed in a case that showed the same neuropathologic alterations, the hypothesis is advanced that the organic changes merely precipitate or sensitize one toward a psychosis the type of which is predetermined by psychologic or constitutional mechanisms

Two cases of disseminated lupus erythematosus with neuropsychiatric symptoms are described by Daly.³⁴ These symptoms included toxic delirium, frank psychosis, coma and convulsions. Characteristically, neurologic examination showed scattered motor, reflex and sensory changes that shifted rapidly on repeated examination. Pathologically, the essential damage to the brain consisted of extensive vascular changes similar to those found elsewhere in the body, with a diffuse type of nonspecific encephalitis.

Yannet and Lieberman³⁵ found the incidence of incompatible mother-child Rh blood typings to be significantly higher in a group of undifferentiated mental defectives than in a control group. This suggests that the cerebral abnormality of some of these undifferentiated defectives is probably related to maternal Rh isoimmunization during pregnancy. Of the 19 cases in the undifferentiated group in which this etiologic possibility existed, 6 cases were found in which either definite or presumptive evidence of maternal isoimmunization was present. The neonatal history in all 6 of these cases was considered compatible with the diagnosis of erythroblastosis fetalis. These children showed disorders of muscle tone, choreoathetosis and cerebellar dysfunction.

Two cases of acute idiopathic porphyria are reported by Denny-Brown and Sciarra.³⁶ In the first case, a brief delirium with tremor, associated with passage of burgundy-colored urine, was followed by recovery. In the second, the more usual abdominal cramps, with delirium, convulsions, severe motor paralysis and passage of burgundy-colored urine, occurred in two attacks separated by an interval of two years. The patient died during the second attack, and pathological examination revealed lesions of an ischemic nature in the peripheral nerves. The possibility of the presence of some locally acting vasoconstrictor substance is discussed in relation to the pathogenesis of the visceral disorders of porphyria.

Hoeffler, Guttman and Sands³⁷ report 27 cases of verified adenoma of the islet cells of the pancreas with symptoms of hyperinsulinism that were carefully studied from the psychiatric, neurologic and laboratory points of view. A variety of neuropsychiatric manifestations was found in all patients, usually clearly associated with the fasting state, with the patients usually aware of this relation, some having increased their food intake to the point of becoming obese in an effort to forestall attacks. The clinical data fell into four groups. The most frequent autonomic visceral symptoms, occurring

in 22 patients, were lightheadedness and sweating, headache and less often abdominal pain, nausea, vomiting, pallor, ravenous hunger and coldness. Somatic neurologic abnormalities were observed in 25 patients. Sixteen had motor symptoms, usually consisting of generalized weakness, tremor and incoordination and less often hemiplegia, — 1 patient had a residual hemiparesis, — diminished or absent reflexes and bilateral Babinski signs. The most frequent sensory symptoms were paresthesias, occurring in 15 patients. Fifteen patients had disturbances of vision or of the extraocular motor system, usually in the form of diplopia, blurring of vision or nystagmus. Five patients had transitory aphasia. Psychomotor symptoms occurred in practically all patients. Most frequently seen were confusional states, dullness and noisy behavior, and less frequently there were inability to concentrate and irritability. Phenomena suggestive of fragmentary or full-blown seizures were noted in 22 patients. Deep coma was seen in 15 patients. Nine showed purposeless random movements, thought by some observers to resemble extrapyramidal dyskinesias. Five patients had fainting spells, 5 had actual grand-mal attacks observed on the wards, and 1 patient had sensory Jacksonian episodes without loss of consciousness. Two patients had staring spells suggestive of petit-mal attacks.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., Editor

BENJAMIN CASTLEMAN, M.D., Associate Editor

EDITH E. PARRIS, Assistant Editor

CASE 32291

PRESENTATION OF CASE

A forty-eight-year-old man entered the hospital because of painless jaundice.

For three weeks before admission the patient was easily fatigued. His weight dropped from 170 to 150 pounds. Three weeks before admission his wife noticed that his skin was yellow, and a physician pointed out that the urine was dark and the stools light. In the last week before admission there was generalized itching of the skin. There had been anorexia for the previous two days, but no nausea, abdominal pain or tenderness, or fever. There had been no previous episodes of jaundice and no history of excessive alcohol consumption.

On physical examination the skin, scleras and mucous membranes were deeply jaundiced. The heart sounds and breath sounds were faint, and the lung fields were hyper-resonant. The neck veins were full in the upright position. The liver edge extended 2 cm. below the costal margin and was not tender. The left border of the prostate felt hard and slightly irregular, but there was no enlargement. There was no edema or ascites. The tongue was normal. The spleen was not palpable.

The temperature was 99.8°F, the pulse 70, and the respirations 20. The blood pressure was 96 systolic, 70 diastolic.

Examination of the blood showed a red-cell count of 4,100,000 and 118 gm. of hemoglobin. The white-cell count was 8000, with 60 per cent neutrophils. The urine had a specific gravity of 1.012 and gave a +++ reaction for bile. The

stools, which varied from clay colored to brown, were guaiac negative on five of eight examinations and positive on the others. A chest film and a gastrointestinal series were negative. The serum bilirubin was 29.9 mg. per 100 cc. direct, and 38.0 mg. indirect, the total protein was 6.9 gm., the albumin 4.2 gm. and the globulin 2.7 gm. per 100 cc. A cephalin flocculation test was \pm at twenty-four hours and ++ at forty-eight hours. The total cholesterol was 255 mg. per 100 cc., with 65 per cent cholesterol esters. The phosphorus 2.8 mg., the non-protein nitrogen 19 mg. per 100 cc., and the alkaline phosphatase 9.2 Bodansky units. The prothrombin clotting time was 20 seconds (normal, 19 seconds). Duodenal drainage yielded colorless fluid with a pH of 7.4, the sediment contained innumerable white cells that were not bile stained, and no cholesterol crystals or calcium bilirubinate pigment was seen.

In the hospital the temperature ranged from 99.8°F to normal and subnormal.

An operation was performed on the fifth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. ALFRED KRANES: This case is fairly typical of a group of cases that to my mind are clinically undiagnosable, usually for quite a long period. The group comprises cases of deep painless jaundice of relatively short duration in which the laboratory findings, physical examination, x-ray films and history are essentially negative. The diagnosis is ultimately made in one of two ways: either by the passage of time during which the patient gets well, or at operation, as in the case under discussion. I am not at all sure that, confronted with a similar problem, I should have had the patient operated on quite so soon. I think that less harm is done by a delay of several weeks than by operating needlessly on a patient with hepatitis. For the problem here is whether this patient had acute hepatitis or obstructive jaundice. Since the advent of vitamin K therapy it is no longer dangerous to postpone surgery for a week or two while the patient is under intensive medical care. On the other hand, it is inadvisable to operate on a patient with acute hepatitis.

The real decision is whether the patient had obstructive jaundice. If he did, the nature of the obstruction is nothing more than a guess. On the whole the evidence favors an obstructive type of jaundice, but I do not believe that one can be certain of that from the evidence at hand.

Reviewing the history and physical examination, one would like to know what this patient's occupation was, to make certain that there were no occupational hazards, so far as liver intoxication is concerned, and whether he was taking any drugs. Presumably neither one of these factors was important in this case, otherwise, it would probably have been mentioned. I am somewhat puzzled about the history. The fact that the patient's weight went from 170 to 150 pounds without any obvious reason is quite puzzling. It is stated that anorexia did not develop until a few days before admission, and yet during the period before admission the patient lost 20 pounds. I am inclined to believe that the disorder of appetite must have been present for a considerable time. One would like to know whether the patient consulted a physician simply because his wife had noticed that the skin was yellow or whether he had symptoms at that time. The statement is made at the beginning that the stools were light colored, and it would help considerably to know whether they remained light colored during that three-week period at home. Later, when he entered the hospital, the stools were not consistently clay colored, so that if any obstruction were present one can assume that it was not constant, since bile pigment was getting through.

The physical examination adds nothing to the picture. The only finding that may need comment is the hard and irregular prostate. It is difficult to believe that that casts any light on the problem, even assuming that the prostate was carcinomatous. I cannot conceive that such a degree of jaundice was caused by metastatic carcinoma of the liver, which rarely produces jaundice, except in the terminal stages, when almost the entire liver is replaced by metastatic tumor tissue.

So far as the laboratory work is concerned, the most important finding was in the stools, which varied from clay colored to brown, indicating that bile was getting through occasionally. The fact that a duodenal drainage done later yielded a colorless fluid simply means that no bile was getting through at that particular time, one must not assume that the obstruction was complete.

I do not know just how to interpret the guaiac-negative and guaiac-positive stools. One naturally assumes that a guaiac-positive stool in the presence of weight loss and intense jaundice signifies some neoplastic lesion in the duodenal region. That is not necessarily true. People with jaundice have guaiac-positive stools. Deeply jaundiced people have a hemorrhagic tendency, although the prothrombin

time in this case was normal. One would like to know how positive the stools were, whether + or ++++. The rest of the laboratory findings except for the van den Bergh reaction are not helpful. One or two straws in the wind point toward an obstructive lesion—the elevated cholesterol and cholesterol ester ratio, and the elevated alkaline phosphatase. Neither one is conclusive, to be sure, but both suggest an obstruction of the biliary tract.

DR TRACY B MALLORY. The guaiac reactions of the stools were + and +++.

DR KRANES. In that case we cannot attach too much significance to the stools. I am still somewhat puzzled and find it difficult to decide whether the jaundice was or was not obstructive. On the whole the evidence is slightly in favor of an obstructive lesion, but I should like to point out that everything recorded could well be found in a case of acute hepatitis. Certainly many patients with severe cases of hepatitis have persistently clay-colored stools. If this patient were twenty-eight years of age instead of forty-eight there would be little doubt about the advisability of waiting to find out what course the disease might take. At the former age acute hepatitis is more frequent than obstructive lesions of the biliary tract. But the patient was forty-eight, and at that age acute hepatitis is less frequent. It does occur, however, and must be kept in mind. At the age of forty-eight, with a history like this, the chances are in favor of an obstructive lesion of the common duct, which is what I believe this patient had, although one cannot be sure.

Having assumed that it was an obstructive lesion, all one can do is guess its nature. There are two main possibilities: obstruction by a stone and neoplastic obstruction of the common duct. We have all encountered cases of gallstone obstruction that were painless, but I should expect some sort of abdominal distress. A complete and totally painless jaundice with stones seems unusual and is unlikely in this case. The betting is somewhat in favor of a neoplastic lesion, probably a carcinoma of the common bile duct or of the ampulla, or a carcinoma of the head of the pancreas. Certainly the weight loss, the clay-colored stools, the elevated cholesterol and cholesterol esters and the positive guaiac tests on the stool make such a diagnosis at this age more attractive than any other diagnosis. Although I still do not know what this man had, the most probable lesion is a carcinoma of the ampulla or bile duct, an obstructive lesion, but it would not surprise me if it turned out to be acute hepatitis.

DR ROBERT S PALMER. Would Dr Kranes consider doing a liver punch biopsy?

DR KRANES. I think that a peritoneoscopy and biopsy of the liver before actual surgery would be a logical procedure rather than waiting too long.

DR MALLORY. A peritoneoscopy was done.

DR. EDWARD B. BENEDICT No lesion was grossly visible in the liver, but we took a biopsy that gave us the answer

DR. MALLORY Unfortunately the biopsy did not exactly give us the answer

DR. BENEDICT At least it gave us a pathological report

CLINICAL DIAGNOSIS

Carcinoma of head of pancreas?

Carcinoma of ampulla of Vater?

Infectious hepatitis?

DR. KRANES'S DIAGNOSIS

Carcinoma of common duct? -

Acute hepatitis?

ANATOMICAL DIAGNOSIS

Infectious hepatitis

PATHOLOGICAL DISCUSSION

DR. MALLORY The biopsy was done during a period when I was absent from the city. The clinicians were impatient for an immediate diagnosis and were content with an oral report from one of the junior men, who believed the lesion to be consistent with obstructive jaundice. Without further delay an exploratory laparotomy was done. No evidence of obstruction was found, and another biopsy of the liver was done. Following operation the patient's jaundice temporarily increased, after which he began a slow but apparently complete recovery and left the hospital entirely well.

When I returned and was shown the first biopsy specimen I considered it reasonably typical of infectious hepatitis. It showed periportal inflammatory infiltration of mononuclear cells, foci of intralobular inflammation and acidophilic necrosis of individual liver cells. In the second specimen the process had cleared to a considerable degree, and the diagnosis was more difficult. I have had the advantage of seeing a large number of biopsies of cases of epidemic hepatitis during my experience in the Army. Before this experience I have no confidence that I should have recognized the lesion. Most pathologists expect to find extensive central necrosis, such as is seen at autopsy in fatal cases. In nonfatal cases this necrosis is rarely found.

DR. BENEDICT How do you explain the marked weight loss and absence of fever?

DR. MALLORY Fever is a variable symptom and is most frequently seen in the prodromal period before jaundice. I cannot explain the weight loss.

DR. KRANES I should like to ask the surgical point of view on how long to wait when it is difficult to decide. What harm comes to these patients under careful observation?

DR. FIORINDO A. SIMEONE The longer one allows the obstruction to continue, the greater the chance of irreparable harm to the liver cells and the more difficult it is to correct a disturbance such as the prothrombin formation.

DR. CLAUDE E. WELCH There is an additional consideration if this had been a carcinoma of the ampulla, it might have passed the curable stage during the period of observation.

DR. KRANES How long would that be? It is difficult to believe, since the patient had been jaundiced for three weeks, that two weeks' observation would make such a difference.

DR. WELCH I should hesitate to wait longer than two weeks. It is a difficult decision to make.

CASE 32292

PRESENTATION OF CASE

A twenty-five-year-old man, a window decorator, entered the hospital because of dizziness, double vision, headache, nausea and vomiting.

The patient had always been in good health except for occasional "sinus trouble," which was never severe enough to cause him to consult a physician. Five years before admission the patient was discharged from the Army because of bilateral otosclerosis and deafness. Six weeks before entry he noted the sudden onset of dizziness while decorating a window. Things seemed to dance up and down in front of his eyes. A physician found "low blood pressure." Five weeks before entry, the patient became aware of diplopia when looking to the extreme right or left. A week later he rapidly developed a severe dull, nonthrobbing, frontal headache. These symptoms persisted, and three weeks before entry he became nauseated and vomited several times. Associated with the dizziness was some stumbling and clumsiness of gait. A week before entry he became drowsy and had difficulty in remembering where he put things. He experienced some chilly sensations but never had a frank chill. Vision was blurred. Four days before entry the nausea had progressed to such an extent that he ate nothing and drank very little. Two days later he was forced to stop work and slept most of the time. He was finally brought by ambulance to the Emergency Ward.

Physical examination revealed a drowsy, slightly obese young man who yawned frequently. Speech was slow but distinct, and he gave an adequate history. The cranium, chest, heart and abdomen were normal. On confrontation the visual fields were normal. The pupils were equal (4 mm) and did not react to light but did react to near vision, although there was absence of convergence. No spontaneous nystagmus was present, but there was nystagmus retractorius of the left eye. Conjugate upward gaze was paralyzed, and downward gaze was weak, lateral conjugate gaze was present to a limited degree. For days all eye movements became progressively weaker and eventually paralyzed. The nystagmus retractorius disappeared, but there was vertical nystagmus on attempted downward gaze. Attempted lateral gaze result-

ed in a slight convergent movement of the left eye. There was no optokinetic nystagmus.

The fundi were normal on admission, but in a week, papilledema (1 or 2 diopters) was present, in addition to a small flame-shaped retinal hemorrhage on the left side that was followed in a few days by a similar hemorrhage on the right. Hearing was markedly impaired bilaterally. The neck was quite stiff. The fifth, seventh, tenth, eleventh and twelfth nerves were normal. There was some unsteadiness in performing the finger-to-nose test on the right, and the Kernig test was positive. The arm and knee jerks were difficult to elicit and were bilaterally equal. The ankle jerks were ++ and equal. There was a flexor-plantar reflex bilaterally.

The temperature, pulse and respirations were normal. The blood pressure was 110 systolic, 60 diastolic.

Examination of the blood revealed a red-cell count of 5,360,000, with 110 per cent hemoglobin, and a white-cell count of 9040, with 76 per cent neutrophils. The nonprotein nitrogen, chlorides, carbon dioxide and fasting blood sugar were normal. Repeated blood cultures were negative. The blood Hinton test was negative. Lumbar puncture yielded an initial pressure equivalent to 215 mm of water and a final pressure equivalent to 130 mm. The spinal fluid was questionably xanthochromic and contained 6 red cells, 45 lymphocytes and 6 polymorphonuclears per cubic millimeter. The protein was 98 mg, the sugar 11 mg and the chlorides 680 mg per 100 cc. The urine had a specific gravity of 1.022 and was normal except for a ++ test for acetone. There was no albumin or sugar. Smear and culture of a pellicle formed on standing were negative for tubercle bacilli. A guinea pig was inoculated. A tryptophane test on the spinal fluid was positive.

A tuberculin skin test was negative in a dilution of 1:1000. X-ray films of the chest and skull were negative. The pineal body was not visualized.

The patient continued to be drowsy but could be aroused. On the third hospital day the temperature suddenly rose to 105°F, and he became stuporous and incontinent. No reflexes could be obtained. The plantar reflexes were flexor bilaterally. He was given alcohol sponges and penicillin. At no time did he receive sulfonamides. The temperature continued to climb, reaching a peak of 107°F on the fourth hospital day. On the sixth day it was down to 99°F, but rose again to 104° in the evening and gradually dropped to 99°, running a moderate spiking course. The state of consciousness approximately paralleled the temperature, but the patient never regained full consciousness. On repeated lumbar punctures the spinal-fluid pressure was equivalent to 230 to 300 mm of water. The fluid was xanthochromic, with 20 to 25 white cells per cubic millimeter, of which a few (1 to 6) were polymorphonuclears. The total protein remained elevated

(56 to 98 mg per 100 cc). The sugar rose to 65 and 89 mg per 100 cc (punctures performed following infusions of 5 per cent dextrose in saline), and the chlorides rose to .827 milliequiv per liter. The gold-sol curve was 0001121100. Dynamics, performed on the fourth lumbar puncture, were normal.

On the twelfth hospital day a red petechial eruption, which blanched on pressure, appeared over the back, dependent regions of the shoulders and upper arms, gradually spreading over the entire body and assuming a maculopapular character. On the following day the nonprotein nitrogen was 205 mg per 100 cc. The patient was totally incontinent, passing many diarrheal stools that were negative for pus, parasites and occult blood. On the fifteenth hospital day the nonprotein nitrogen had risen to 260 mg per 100 cc. The carbon dioxide was 12.1 milliequiv and the chlorides 104 milliequiv per liter. An indwelling catheter was placed, and although oliguria had been suspected the measured output rose to approximately the intake. The specific gravity was 1.010 on repeated examinations, and a ++ test for albumin was found. Abundant colon bacilli were grown in urine culture. Repeated chemical determinations showed continued high nonprotein nitrogen, reaching 290 mg per 100 cc on the twentieth hospital day. The carbon dioxide content, however, gradually rose to 20.9 milliequiv per liter. On the sixteenth hospital day an x-ray film of the chest revealed a definite increase in density in the left-lower-lung field. Moist rales became audible at the left base, and the patient developed chills and rapid, shallow respiration. His condition grew rapidly worse, and he died on the twenty-fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR MANDEL COHEN This man was apparently well until the onset of the present illness and over a period of six weeks developed, successively and rapidly, dizziness, slight diplopia, nausea, vomiting, stumbling and drowsiness. He was taken to the hospital, where it was found that he had some signs indicating that the midbrain and the cerebellum were involved. A few cells were found in the spinal fluid, and there was fever. The question no doubt came up whether the disorder was infection or neoplasm. He became worse and, after being in the hospital for twelve days, developed nitrogen retention and a rash. Nitrogen retention progressed, and death followed.

From these data it is not possible to determine exactly the nature of this disorder. There were, however, signs and symptoms that point fairly definitely to the location and that give a lead regarding the possible causes of the lesion. To begin with, the symptoms of dizziness, diplopia, nausea, vomiting, stumbling and drowsiness could be related to disease involving the cerebellum or cerebellar connections. The neurologic examination showed

predominantly difficulties with eye movements that were not paralysis of isolated nerves but concerned conjugate movement, upward movement, downward movement and lateral movement, in addition, the pupils measured 4 mm and did not react to light, but did react during accommodation. Convergence of the eyes was absent. All that taken together means that the midbrain was involved. Was it involved by a mass in the midbrain, or was it involved by something pressing on the midbrain? I cannot tell the difference. Incidentally the patient had nystagmus retractorius. After a certain amount of investigation and aid from Dr. Cogan, I discovered the meaning of this term. When co-ordination of eye movements is poor all the muscles may move together. An attempted eye movement results in eye retraction, this is supposed to be due to distribution of connections of the nuclei of the third nerve. All these eye signs point definitely to disorder affecting the midbrain. One might ask why we did not think that the nerves individually were involved. The patient did not have obvious strabismus, it was not possible to demonstrate isolated paralysis of nerves, and the eyes followed objects. Midbrain localization was therefore indicated. It is probable that the lesion or lesions were in the neighborhood of the midbrain and the anterior part of the cerebellum.

The next question to decide is the nature of the disorder. Because of the progressive course, this disorder probably was not a thrombosis of the blood vessel or vascular disease, because of the evidence of increased intracranial pressure and the lack of other typical signs, it was probably not any of the so-called "degenerative diseases," such as acute encephalomyelitis and multiple sclerosis. That leaves the problem of what could cause increased intracranial pressure and develop rapidly within about six weeks, with death following soon thereafter. It seems to me that one cannot tell absolutely whether this was a tumor or an infectious disorder. The course of the illness, which was rather brief for that of tumor, suggests some infectious disorder. Neoplasm involving the area of the midbrain, however, often runs a rapid course. In Dandy's¹ series some tumors of the third ventricle ran half a year's course between the first symptom and operation. The short course is therefore not diagnostic, except that it is somewhat short for a tumor.

In considering infectious disorder of the brain, one must include an infectious mass—that is, abscess or tuberculoma. One would then like to have some idea of what such a mass is secondary to, because by and large, if a patient has brain abscess or tuberculoma, there is some evidence of primary infectious disease. There was no evidence of tuberculosis in the lungs or elsewhere or of a focus of infection suggesting a brain abscess. Five years before admission the patient was discharged from the Army because of bilateral otosclerosis and deaf-

ness. I wonder whether he had bilateral otitis media all the time, but I assume that the ears were examined in this hospital and were normal. Apparently this patient's "sinus trouble" was never severe enough for him to consult a physician. That type of history is of no help in an attempt to find the focus of infection for brain abscess. Usually clear-cut evidence of otitis media, sinusitis or lung disease is found, but this patient did not have such evidence. That is a serious drawback to the diagnosis of infection, such as abscess.

Does the fever help in the differential diagnosis? By and large, it is safe to assume that if the patient had fever he had infection. One serious exception, however, is when a patient has disease around the midbrain and hypothalamus, which I suppose is exactly where the disease occurred in this patient. There are well authenticated cases of continuous fever from lesions in that region. In general, most diagnoses of neurogenic fever and probably all so-called "psychogenic fever" lead to the wrong answer. Consequently even fever does not help in the decision between tumor and infection.

Does the spinal fluid help in the differential diagnosis? The few cells make one think not of obvious meningitis but of a mass like abscess or tuberculoma that is irritating but does not actually infect the ventricular and subarachnoid spaces. Tumors, particularly those involving the third ventricle or other ventricles, also give a few cells and even a few polymorphonuclears. What about the spinal-fluid sugar? In general, a low spinal-fluid sugar means the active presence of bacteria, tubercle bacilli or yeast. The first sugar determination was quite low (11 mg per 100 cc), and subsequent tests were within normal limits. One possibility is that the first sugar determination was wrong—that the fluid stood for a day or two before analysis.

DR. JAMES MEATH: The first sugar determination was done on the day following lumbar puncture.

DR. COHEN: The lumbar puncture was done, and the fluid stood over night and was analyzed later. Falsely low sugars can be obtained under such circumstances. That is quite possible in this case because the cells were not high enough to go with such a low sugar. The blood sugar level affects the spinal-fluid sugar with a high blood sugar after a clysis or intravenous injection the spinal-fluid sugar may be falsely high. In bacterial infection it is also possible for patients being treated with penicillin to have bacteria in the spinal fluid, the sugar remaining high in the presence of penicillin. Apparently under these conditions bacteria are not able to use sugar. All one can say is that the patient had one quite low sugar and two normal ones. In tuberculous meningitis, if the sugar is once low, it is apt to remain low. The cultures, I gather, were all normal. Were cultures taken of the spinal fluid when the patient was not getting penicillin?

DR. MEATH: Yes.

DR COHEN Final conclusions cannot be drawn from a good part of the data. One must say that the course could be tumor or infection, and the spinal fluid could go with either. There was no good source for infection.

We are left with the possibility of a mass that was in the cerebellum, pressing on the midbrain or, less likely, in the midbrain itself and was either neoplastic or infectious in origin. If infectious, the mass was probably tuberculoma or something of that sort rather than an abscess.

The neurologic disorder progressed, and on the twelfth day a petechial eruption of a maculopapular character developed, from that point on nitrogen retention was noted. The nonprotein nitrogen rose steadily, and there were acidosis and diarrhea. All we are told about renal studies is that cultures gave abundant colon bacilli. The patient presumably did not have pus in the urine. Is that right?

DR TRACY B MALLORY When he first came in he had a specific gravity running from 1.020 to 1.030, with no albumin and only one or two white cells per high-power field on smear. Terminally, after he had an indwelling catheter for many days, there was pus in the urine.

DR COHEN The patient then developed what seemed to be pneumonia and died. How can one relate this development of uremia with the intracranial disease? One can speculate about various syndromes associated with brain and renal disease, but none of them seem clinically applicable in this case. Could there have been hypertension or vascular disease of a malignant type, which led to brain lesions and then to renal failure? This case does not give the picture of that syndrome, either by course or by signs. Another possibility is a renal tumor that metastasized to the brain and later showed itself as renal disease; again, there is no evidence whatsoever. Other conditions such as periarteritis nodosa which involve the brain and kidney, can be mentioned, but there is no evidence.

Were any drugs besides penicillin given?

DR MALLORY No.

DR COHEN Does penicillin, like the sulfonamides, cause uremia? The only evidence is that nitrogen retention occasionally occurs during the administration of penicillin, but for all practical purposes a renal complication is not attributable to penicillin.

Could this patient have had a bacterial infection, septicemia, brain infection and, terminally, renal infection? Again, there is no evidence. I gather that there was no retrograde pyelogram or anything like that, which might have helped somewhat.

Could tuberculosis of the kidney have been associated with the alleged tuberculoma of the brain? That is not likely, the uremia would not be consistent with the brain disease. Perhaps cystitis and pyelonephritis developed terminally. That is not a satisfactory explanation, but I do not see any other, in the absence of drugs such as sulfanilamide.

In conclusion, this man had a disease that came on fairly rapidly and seemed to involve the region of the cerebellum and the midbrain, causing increased intracranial pressure, fever and cells in the spinal fluid. Further information in such a situation could be obtained from injections of air into the ventricles. I suppose that procedure was done. There was a mass, in all likelihood in the neighborhood of the cerebellum and the inferior cerebellum peduncle or, possibly, in the midbrain, it could have been a pinealoma that was pressing on the brain stem. I cannot go any farther from the evidence.

Since I must make a definite diagnosis, I believe that the patient had a brain tumor, and my second choice is tuberculoma.

DR MALLORY There are two very definite phases to this case, the cerebral and the renal. Dr Dahl, will you give the impression on the wards?

DR LEWIS K DAHL Dr Burnett actually followed the case. None of us suspected what was really found. I think that the most prevalent opinion on the wards was that this was periarteritis nodosa, because of the hypertension and the renal and cerebral signs.

DR JAMES B AYER Is the record here? May we see the temperature chart?

DR MALLORY The printed record does not give any idea of the extreme elevation of temperature. On the ninth hospital day the temperature was normal, on the tenth it was 105°F, and on the morning of the eleventh it was 107°F, despite practically constant alcoholic sponges, ice packs and so forth, dropping on the following day back to 99°F — a severe and prolonged hyperthermia.

DR WYMAN RICHARDSON May we see the x-ray film of the chest?

DR JAMES R LINGLEY This film, taken with a portable apparatus, shows a great deal of motion. There is a small area of density, however, at the left base consistent with consolidation. This film was taken just before death.

CLINICAL DIAGNOSES

Tuberculous meningitis?
Periarteritis nodosa?
Subacute bacterial endocarditis?
Brain tumor (pinealoma-lesion in midbrain)?
Toxic nephritis

DR. COHEN'S DIAGNOSIS

Brain tumor (? pinealoma)
Tuberculoma?

ANATOMICAL DIAGNOSIS

Pinealoma

PATHOLOGICAL DISCUSSION

DR MALLORY I shall discuss the renal situation first and let Dr Kubik tell us what was found in the central nervous system.

The kidneys showed a lesion that has become familiar during and since the war. There was a frank

hemoglobinuric nephrosis, with degeneration in the lower segments of the nephrons, a considerable amount of interstitial nephritis and precipitation of hemoglobin pigment in the tubules. The kidney was of the type seen with mismatched transfusion, crush syndrome, blackwater fever, burns and a number of other situations. A fairly frequent cause of such a renal injury is sulfonamide sensitivity. This man, we know, had received no sulfonamides. In the kidneys there were some questionable crystals, but on analysis in the chemistry laboratory no sulfonamides were found. The sulfonamides can therefore be completely ruled out. There had been no transfusion, no plasma and no obvious cause of hemolysis.

At the United States Army Institute of Pathology in Washington there were 120 fatal cases of heat stroke. In that group, 10 or 15 patients developed severe hemoglobinuric nephrosis and died in uremia several days after recovery from the heat stroke. In some of those cases, despite a clinical state of shock, neither whole blood nor plasma was used in treatment. Nevertheless the patients showed massive precipitation of hemoglobin in the kidneys. That is the only explanation one can find for this case. The hyperthermia was so marked that the same physiologic mechanism seen in heat stroke might easily have been involved.

DR. CHARLES L. SHORT: In artificial-fever therapy patients have been subjected to temperatures of 106.7°F for eight hours in this hospital and in Rochester, New York, by Dr. Stafford L. Warren for thirty hours, but I remember that no cases of this syndrome were found. The patients were in reasonably good physical condition.

DR. MALLORY: The lesion is one that has been generally recognized by pathologists only within the last few years, so that I hesitate to accept a case reported over five years ago. It was probably not the hyperthermia but the subsequent shock that was responsible.

DR. CHARLES S. KUBIK: This was a tumor of the pineal region, which, I have been told, was the diagnosis made on admission by one of the house staff, who based his opinion on the defective upward conjugate movement of the eyes. This, as Dr. Cogan said in discussing another case,² is practically always a dependable sign of a lesion involving the quadrigeminal bodies and, in my experience, has occurred most frequently through, although not exclusively with, pinealomas and tumors in the pineal region. In this case subsequent findings and developments made the diagnosis more difficult.

On sagittal section of normal brain showing the relations of the pineal body, which is situated in the midline immediately above the superior quadrigeminal bodies and at the posterior extremity of the third ventricle just above the anterior end of the aqueduct, the pineal recess of the third ventricle actually dips into the pineal body. The spinal fluid is formed in the lateral ventricles, passes through the foramen of Monro into the third ventricle, and

thence through the aqueduct into the fourth ventricle from which it enters the subarachnoid space through the foramina of Magendie and Luschka. It is readily seen why tumors in the pineal region lead to internal hydrocephalus by obstruction of the aqueduct.

In the brain in the case under discussion, behind the optic chiasm, there was a rounded prominence 1.3 cm. in diameter, which represented the floor of the third ventricle; it bulged downward because of dilatation and was also invaded by tumor. Horizontal sections of the brain showed the tumor, measuring 2.5 to 3 cm. in diameter, in the pineal region. It extended forward in the third ventricle between the optic thalami, which it invaded. It also extended downward, invading the tegmen of the midbrain and completely filling the aqueduct and the upper part of the fourth ventricle.

Anterior to the main tumor mass, the ependyma of the third ventricle and of the anterior horns of the lateral ventricles was covered with tumor implants. Implants in the third ventricle in these cases are fairly frequent and sometimes, through involvement of the hypothalamus, lead to diabetes insipidus, even when there are no clinical indications of tumor in the pineal region. There was no diabetes insipidus in this case, but the tumor involvement of the hypothalamus probably accounted for the fever.

Of the several pinealomas examined, all invaded the midbrain, none could have been removed by operation.

Histologically the tumor in this case was composed of rather large, rounded and fusiform cells with well defined cytoplasm and also of cells with poorly defined cytoplasm. An unusual feature was the presence of multinucleated cells and many giant cells, some of which had as many as twenty visible nuclei. I believe that these were tumor cells and not foreign-body giant cells.

The histologic findings were somewhat different from those observed in other cases of pinealoma, which are usually composed of fairly large rounded and polyhedral cells and are frequently infiltrated with lymphocytes and sometimes with lymphocytes and plasma cells. In the case recently discussed by Dr. Cogan² the tumor cells resembled very closely the cells of the normal pineal body, and there was little or no infiltration with lymphocytes.

In this case the fusiform and giant cells were unusual, but the gross findings were similar to those of pinealoma, indicating that the tumor began in the pineal region and later invaded the midbrain and optic thalami. Fusiform and giant cells are frequent in some of the gliomas, and since the parenchymal cells of the pineal body are derived from glial cells I suppose that similar de-differentiation occurs in a pinealoma.

"LETHEON"

THE present year is one that merits more than ordinary consideration in the history of surgery and in the annals of the Massachusetts General Hospital, for it was one hundred years ago this fall, in the surgical amphitheater then under the hospital's glass-topped dome, that painless surgery was given its first public demonstration, and a new surgical era began. In 1921, with fitting ceremonies, the hospital observed its own one hundredth anniversary, on October 16, 1946, it will celebrate the centenary of its greatest single service to humanity.

The properties of sulfuric ether were far from unknown when William Thomas Green Morton, the Boston dentist, administered that volatile sub-

stance, sometime known as "Letheon," to Gilbert Abbott in order that John Collins Warren might painlessly remove a tumor from under the jaw. In the late eighteenth century there is an account of its use in a case of "pectoral catarrh," when two teaspoonfuls were volatilized and inhaled with considerable benefit to the sufferer, its employment was again reported, about the turn of the century, "for the relief of a very painful inflammatory affection of the mamma." We may further read, in Pereira's *Materia Medica*, published in London in 1839, that "the vapor of ether is inhaled in spasmodic asthma, chronic catarrh, and dyspnoea, hooping cough, and to relieve the effects caused by the accidental inhalation of chlorine gas."

We have Dr. Charles T. Jackson's own word for it, in a statement issued in 1847, that he had experimented with ether in 1841, and it is generally recognized that Dr. Crawford W. Long, a physician of Georgia, had used ether as a surgical anesthetic as early as 1842, although he made no public announcement of his experiences until 1849.

Sulfuric ether was not the only volatile substance whose anesthetic properties were the subject of early experimentation. Sir Humphry Davy, the noted English chemist and physicist, had investigated nitrous oxide in 1799 and suggested the use of this gas in surgical operations "attended with little effusion of blood." Horace Wells, a dentist of Hartford, formerly associated with Morton, had later experimented with the gas and had given an unsuccessful demonstration of its use in 1844. The year after ether made its debut Sir James Y. Simpson, of Edinburgh, introduced chloroform as a general anesthetic.

The recognition of anesthesia as the great turning point in surgery took place in the Massachusetts General Hospital. Its official announcement to the medical profession was made through the medium of the *Boston Medical and Surgical Journal*, on November 18, 1846, in the article "Insensibility during Surgical Operations Produced by Inhalation" by Henry Jacob Bigelow, one of the surgeons of the Massachusetts General Hospital. The *Journal* had more on the same subject in the following months, and the hospital report of 1848 announced a total of one hundred and thirty-two

operations performed within its walls using ether as an anesthetic

The ignominious controversy that raged for a time over the credit for the ether discovery takes away nothing from the importance of the event itself. Morton wanted credit and gold, and Dr Charles T Jackson, whose student in chemistry he had once been, put in his claim for a major share of the honor of the discovery. The anesthetic was patented jointly by Morton and Jackson on condition of the latter that he receive one tenth of the profits, and the Board of Trustees of the hospital presented a purse of \$1000 to Morton in 1848. It is not the way things are done today, and Bowditch* no doubt wrote earnestly in his history of the hospital, first published in 1851, that "the patience of the public has been long since thoroughly wearied out by the ether controversy."

The fact remains that through a long one hundred years we have had the blessing of painless surgery, with the refinements that the years have brought to it. We have had the accumulated benefit to those countless surgical patients who have found in anesthesia something like the music of the Lotos-Eaters, to wax poetical

Music that gentlier on the spirit lies,
Than tired eyelids upon tired eyes,
Music that brings sweet sleep down from the
blissful skies

DISABILITY FOLLOWING ACUTE HEPATITIS

THE persistence of liver damage after apparent recovery from acute infectious (epidemic) hepatitis or so-called "catarrhal jaundice," has recently received a certain amount of attention.

Salmon and Richman¹ reviewed some of the recent literature on the subject and reported follow-up studies on 16 characteristic cases. They found liver damage demonstrable by the cephalin-cholesterol flocculation test and by a lowering of the diastatic activity of the serum, which persisted for a period varying from a few weeks to several months after apparent recovery from the acute attack. Others

have demonstrated impairment of liver function by various tests in from 25 to over 60 per cent of patients for periods varying up to several years.

Caravati² noted a clinical syndrome in a number of enlisted men and officers as a sequel to homologous serum hepatitis that followed vaccination against yellow fever. The subjective symptoms of this syndrome were chronic fatigue, discomfort (a mild but constant aching) in the right upper quadrant of the abdomen, digestive disturbances (flatulent dyspepsia) especially after the ingestion of fats, malnutrition and failure to gain weight even on a high-calorie, high-vitamin diet and emotional instability. Studies of these patients revealed no hypoproteinemia, hypocalcemia or anemia, and there was no evidence of vitamin deficiency of any type. Gastric secretion and motility were found to be normal, although some showed a slight degree of hypermotility of the small intestine that was not enough to be considered significant. Studies of pancreatic function in several cases revealed no abnormality. The liver was found to be normal in size, shape and contour, and only a single patient showed evidence of liver disease, as indicated by spider angiomas over the trunk. Various liver-function tests showed no convincing evidence of residual hepatitis or of biliary-tract disease. Caravati believes that this clinical pattern is a constant finding only in such cases and that it does not follow other types of infectious hepatitis. He considers the syndrome to be an alteration of physiology caused by a mild infectious process and by an unfavorable psychic reaction to confinement by long illness. He does think, however, that the liver is probably the source of the physiologic disturbance.

Benjamin and Hoyt³ made a study of 200 soldiers who were returned to the Lovell General Hospital because they had failed to achieve satisfactory convalescence after an attack of jaundice following yellow-fever vaccination. These cases represented only a small proportion of those who originally suffered from postvaccinal hepatitis. They had been in overseas hospitals for several months, and some of them still appeared definitely ill when they arrived, in spite of the fact that five to nine months had elapsed since their original attack of jaundice. As a group these patients were described as "pale,

thin, exhausted and utterly devoid of animation, their reactions, mental and physical, were slow and indifferent." They had had no military training whatsoever since their original illness. Their complaints were extreme weakness, overpowering fatigue, indigestion (particularly for fatty foods), anorexia, pain (especially in the right upper quadrant), nausea and vomiting, backache, insomnia,

nervous irritability and tremors, and anxiety and apprehension (fear of recurrence of jaundice).

From the study of these patients, Benjamin and Hoyt concluded that psychoneurotic patterns may develop as a complication of postvaccinal hepatitis or that antecedent patterns may be reborn. The bromsulfalein test for liver function showed retention of the dye in 32 per cent after twenty minutes and

in 11 per cent after thirty minutes. None of the other patients had objective evidence of liver dysfunction. Improvement in damaged liver functions was still apparent at the end of six months to a year. There did not seem to be any correlation between the laboratory tests and the incidence of palpable liver edges. In 37 patients there was a vasomotor disorder, manifested by pronounced tremor, cold, red, dripping hands and overpowering weakness.

In the course of a study of acute infectious (epidemic) hepatitis in the Mediterranean Theater, Barker, Capps and Allen⁴ observed that certain patients failed to recover promptly and for prolonged periods exhibited symptoms and findings that indicated persistent hepatic disease, with a tendency toward exacerbations and remissions. These cases presented a sufficiently distinctive and uniform clinical picture to justify their consideration as a separate group or syndrome, which they called "chronic hepatitis." In the 76 cases that they studied, the most characteristic and diagnostic feature was the increase in abnormal physical find-

ings, symptoms and laboratory evidence of liver dysfunction produced by exercise. Frequently a patient appeared to have recovered while on minimal exercise, but an increase in physical activity promptly caused the clinical syndrome to reappear. They considered that the essential treatment was adequate bed rest and a high-protein diet. They made an important distinction between active and

inactive hepatitis. The latter group includes patients with objective liver disease but a normal reaction to exercise. In such a situation the symptoms are not disabling, and they believe that no treatment is necessary.

In a paper recently presented at the Harvard Medical Society, Jersild described a number of cases of subacute or chronic hepatitis that occurred in Denmark

during 1944-1945, when there was a widespread epidemic of infectious hepatitis similar to those that occurred in other European countries. In some of the Danish cases the disease started in the usual manner and progressed continuously, whereas in others there was definite temporary improvement, after which the disease relapsed and then progressed. The condition was associated with a high fatality rate and usually occurred in women over forty years of age. Polack⁵ in 1938 described a similar but less severe condition in young adults in Copenhagen after mild attacks of infectious hepatitis.

From all these observations it appears that, although, on the whole, infectious hepatitis and homologous serum jaundice are relatively mild diseases and are associated with an extremely low mortality rate (about 0.2 per cent), cases do occur in which there is a long disabling illness with a variety of symptoms referable to the liver or nervous system or both. It also seems likely that in some of the cases of chronic hepatitis, such as those recently observed in Denmark, and in some of the cases of

MASSACHUSETTS MEDICAL SOCIETY POSTWAR LOAN FUND

The Postwar Loan Fund has been set up, and all discharged medical officers who were members of the Massachusetts Medical Society in good standing at the time of their entry into the service may apply for loans from this fund. For further information apply to

Boston 15, Massachusetts

homologous serum jaundice the infectious agent is one that gives rise to persistent and diffuse residual damage or to a progressive hepatic lesion oftener than does the etiologic agent associated with the usual case of infectious hepatitis or catarrhal jaundice. The implications for treatment are obvious. Patients with residual liver damage require particularly long periods of intensive dietary therapy, with avoidance of exercise beyond their tolerances.

MASSACHUSETTS MEDICAL SOCIETY

SUBCOMMITTEE ON VETERANS' AFFAIRS, POSTWAR PLANNING COMMITTEE

In March, 1946, the Subcommittee on Veterans' Affairs was appointed as a part of the Postwar Planning Committee of the Massachusetts Medical Society. This is in accordance with the sound administrative policy that limits the number of standing or special committees and provides for subcommittees of general committees for specific problems. The subcommittee, composed of five physician-veterans of World War II has met frequently, both independently and in connection with meetings of the Postwar Planning Committee.

The members of the subcommittee were pleased to find that for the past two years or more the Massachusetts Medical Society, through its officers and committees, has attempted to find solutions for the various problems that it was anticipated doctors might encounter on return from service to civilian practice. Foremost of these was judged to be that of postgraduate education and training. In addition to setting up courses of lectures and clinical demonstrations in the seven districts into which the state was divided, the committee arranged for the course of lectures held from February to May, 1946, in Sanders Theater, Cambridge. The latter course proved highly successful, with attendances at the lectures ranging from 400 to 800 physicians. Of these approximately 35 per cent were veterans, a ratio lower than had been anticipated. The second major achievement of the Postwar Planning Committee was the development of the Bureau of Clinical Information at the Headquarters of the Society, designed to serve as a clearing house for

information regarding clinical lectures, ward rounds, operations and so forth that are held daily at hospitals in the Boston area. The bureau has published monthly a mimeographed schedule giving such data in detail for the convenience of veterans and other visiting physicians. The service has been used widely and has received much favorable comment. An unlooked-for development was the demand for a counseling service, which the bureau has supplied so far as its facilities have permitted. Attention should also be directed to the Loan Fund, which is available to all veterans who need it.

From the time of its organization, the Subcommittee on Veterans' Affairs has attempted to find out what other problems were of most concern to returning doctors and has tried to find solutions for such of these as were capable of solution by Society action. Information has been gained from personal interviews, from informal discussions and from questionnaires distributed at the meetings at Sanders Theater and at the annual meeting of the Society. In addition to the all-important matter of postgraduate training, including refresher courses of varying length, residencies and assistant residencies and so forth, the most frequent problems have appeared to be suitable locations for men starting out in practice or changing place of practice from that prior to military service, availability of assistantships for men starting out in practice, hospital-staff appointments, to provide some place for hospitalization of private patients, office space and homes, telephone listings, and rebuilding of practice.

To provide readily available and up-to-date information regarding locations for practice, assistantships, opportunities in industry and so forth the subcommittee has recommended that the Bureau of Clinical Information be expanded and made a permanent installation of the Society, with sufficient personnel, both professional and secretarial, and sufficient space and funds to render this valuable service not only now but in the years to come. This has been agreed to in principle for the coming year by the appropriate authorities. Although most veteran doctors now out of the service have become settled or soon will be, it is believed that the demand for information of the sort outlined will always be great and that it is a natural function of the Massachusetts Medical Society to furnish such, even though it involves considerable expense. There are still in the service thousands of doctors, some of whom will not return to civilian life for two years or more.

The problem of hospital-staff appointments is far from easy. Hospitals in Massachusetts, in common with those all over the country, are filled to capacity constantly and have long waiting lists of patients. Doctors already on the staff have great difficulty in getting their patients in, even when the need for hospitalization is urgent. Nevertheless, the sub-

committee believes that every effort should be made by hospitals to grant staff appointments, even though of temporary nature or on the courtesy staff, to qualified doctors so that the profession will not be in the position of penalizing men for having spent from two to five years in the services. Already the president of the Massachusetts Hospital Association has sent communications to all hospitals of the Commonwealth urging that particular consideration be given to qualified veteran doctors applying for staff appointments. This supplements similar letters sent long before V-J Day by the Postwar Planning Committee to hospital superintendents, chiefs-of-staff and presidents of boards of trustees of all Massachusetts hospitals. It is earnestly hoped that all hospitals will co-operate in this important matter.

The matter of office space and homes, although acute everywhere, has not appeared to be insurmountable. It is a local problem that has almost invariably yielded to industrious search on the part of the returning veteran. Often he has not been able to secure exactly the type of office and home that he desires, but he has been able to get some type of satisfactory arrangement. The subcommittee urges that each physician having ample office space share it with a returning doctor until such time as the veteran is able to find an office for himself.

Because of the shortage of paper, telephone directories cannot be printed so often as in prewar days, consequently, some physicians will have to wait for some months before being listed. In conferences with the subcommittee, representatives of the telephone company have been most sympathetic and co-operative. The problem, however, is large and involves not only doctors but also other professional and business groups. The best solution at the moment is that returning doctors, when established, take steps to inform their patients of their new address and telephone number. The telephone company has increased its information service and states that within twenty-four hours of the installation of a telephone, the number can be secured through such service. Detailed information on this point was published in the April 18, 1946, issue of the *New England Journal of Medicine*.

The matter of rebuilding of practices and the regaining of patients is a personal, local matter. The subcommittee urges that doctors in a community take pains to inform patients acquired during the war years with the fact that their doctor has returned from the service. The subcommittee believes that no official action of the Society is appropriate in this connection.

It is of importance that all veteran physicians inform themselves on the various activities of the Society in their behalf. Many members of the Society have been in contact with younger graduates

who have not yet become fellows. It is important that these young men be brought into the Society as soon as they have fulfilled the requirements. Who better can bring this before them than those members with whom they served?

* * *

All the preceding was accomplished by the work of the original small committee. At the annual meeting a group of veteran doctors held a meeting to see what further could be done for veterans. At the suggestion of this group each district was asked to appoint a representative to attend a meeting of the Subcommittee on Veterans' Affairs on June 24. At this meeting it was suggested that the original committee be enlarged to include at least one representative from each district. This was promptly accomplished, since the president of the Society was present and immediately appointed the representatives present. There was a long and free discussion of all veteran problems, from which concrete proposals emerged for further action on the part of this subcommittee. These may be briefly summarized as follows:

Education. It was suggested that the course at Sanders Theater be repeated (this has already been planned for) and that courses throughout the state outside of Boston be increased in number and more widely spread. It was also suggested that a two-week graduate course of intensive character be provided at some favorable spot where vacation and work could be combined—something in the nature of a medical Chautauqua. Camp Edwards was suggested as a place for such a course. (This suggestion will be submitted to the subcommittee on graduate education for consideration.)

Automobile procurement. It was decided to write to the larger companies to see if it is possible to secure priority for veteran physicians needing new automobiles.

Hospital seniority. This was discussed at some length. Contact will be made with the Massachusetts Hospital Association to discuss what steps can be taken to assure returning doctors of their former staff priority.

All agreed that the most important function of the Subcommittee was to discuss problems that confronted the medical veterans. To this end all veterans are urged to communicate any problems or suggestions that they think are worthy of study or susceptible of solution by Society action to the district representative on the committee or directly to the chairman. The list of district representatives who have been appointed appeared in the July 11 issue of the *Journal*.

THE TREATMENT OF MENINGITIS DUE TO *HAEMOPHILUS INFLUENZAE* WITH STREPTOMYCIN*

A Report of Nine Cases

LOUIS WEINSTEIN, M.D., Ph.D.†

BOSTON

INFECTIONS with *Haemophilus influenzae* in children constitute a serious problem. In adults, because of the presence of large amounts of potent bactericidal antibodies in the blood, this organism is much less frequently an instigator of disease processes.¹ During the pandemic of influenza in 1918, however, there were many cases in which the hemophilic organism was isolated from the lungs. It therefore appears that the normally present humoral protection against *H. influenzae* may break down under certain conditions and that this type of infection may be of great importance in all age groups. In children, there is no part of the respiratory system that is immune to invasion by this bacterium, and regardless of the location of the disease, the process is always serious and produces a high mortality rate unless promptly and efficiently treated. The other important type of infection produced by *H. influenzae* is meningitis, occurring most frequently between the ages of three months and two or three years, practically all these cases are due to organisms belonging to Type B of Pittman.²

The mortality rate in untreated cases of *H. influenzae* meningitis is between 92 and 100 per cent for all age groups. Weiss and Huntington³ found the death rate to be 80 per cent in a group of 127 patients who were more than two years of age. Treatment with horse serum alone, with horse serum and complement and with sulfonamides alone or in combination with horse serum has produced little effect, and according to Fothergill,⁴ the mortality rate ranges from 54 to 82 per cent in patients receiving these types of therapy. The most effective method of treatment of influenzal meningitis is

that devised by Alexander.⁵⁻⁷ This consists of the use of rabbit serum containing antibody against Type B organisms together with sulfadiazine. With this therapeutic regimen, the mortality rate was reduced by Alexander to 26 per cent in a group of patients ranging in age from three months to over five years, in those over seven months of age, the death rate was only 18 per cent.⁸

Although the results obtained by the use of type-specific antiserum and sulfadiazine are striking, there are still an appreciable number of deaths from influenzal meningitis treated in this manner. Furthermore, the employment of heterologous serum always carries with it the risk of immediate or late reaction owing to hypersensitization. The development of a nontoxic, nonsensitizing, easily given chemotherapeutic agent that can cure influenzal meningitis in as great a percentage as that achieved by Alexander's method or, if possible, in a larger number of cases of the disease appears to be most desirable.

In 1944, Schatz, Bugie and Waksman⁹ reported the isolation of a new antibiotic agent from *Streptomyces griseus*, streptomycin, which was active against some gram-positive and many gram-negative organisms. Birmingham¹⁰ has shown that *H. influenzae* is inhibited by streptomycin in a range of 1:56 to 5 gamma. Little information is as yet at hand regarding the effectiveness of streptomycin in the therapy of *H. influenzae* infections in man; but several reports have appeared in the literature indicating that this agent may be of value in such cases. Birmingham¹⁰ and Smith¹¹ have both reported recovery from influenzal meningitis following administration of streptomycin alone. The use of insufficient doses of the drug appeared to lead to the development of drug fastness in the causative organism. Both these investigators believe that the optimal treatment of influenzal meningitis should comprise streptomycin combined with sulfadiazine or serum or both and that the antibiotic agent should be given both intramuscularly and

†Assistant professor of medicine, Boston University School of Medicine; visiting physician, Haynes Memorial Hospital; instructor in infectious diseases, Harvard Medical School.

intrathecally. Most recently, Herrell and Nichols,¹² in a discussion of the clinical use of streptomycin in various conditions, have reported recovery in 4 cases of influenzal meningitis, 3 of which were due to Type B, the other being caused by an untypable strain, 2 of the patients received additional forms of treatment. The immediate results in all the cases were good, but 1 patient died two months later of a postmeningitic hydrocephalus.

The purpose of the work reported here was to determine the effect of streptomycin on the clinical course of influenzal meningitis, to study the rate of disappearance of the causative organism from the blood stream and spinal fluid and to note any toxic effects that might result from the use of large amounts of the drug.

METHODS

Streptomycin therapy was not started in any patient until the diagnosis of meningitis due to *H influenzae* was established by bacteriologic methods. In a few cases, the causative agent was detected on direct examination of the spinal fluid by the production of capsular swelling with Type B antiserum. In several cases, because of the absence of organisms in gram stains of centrifuged sediment of the spinal fluid, it was impossible to make an etiologic diagnosis until two to three days had elapsed. It was not deemed justifiable to withhold all therapy in cases in which the causative organism could not be detected early in the course of the illness, because all the patients had obvious purulent meningitis. Therefore, chemotherapy other than streptomycin was given until *H influenzae* was isolated, but a period of at least twenty-four to forty-eight hours was allowed to elapse without any type of treatment before streptomycin was given. In this way, it was hoped to avoid treating patients with more than one agent at a time. In all the cases in which treatment was withheld for twenty-four to forty-eight hours, the presence of *H influenzae* in the spinal fluid was confirmed before streptomycin was started.

Streptomycin was administered by two routes, intramuscularly and intrathecally, in a daily dosage of 120,000 to 1,000,000 units by the former route and one of 10,000 to 100,000 units by the latter. The intramuscular injections were spaced at three-hour intervals and each consisted of 15,000 to 125,000 units, whereas the intrathecal ones contained 10,000 to 100,000 units and were given once every twelve to twenty-four hours. Treatment was continued for seven to nineteen days intramuscularly and for at least four to seven days longer intrathecally. Samples of serum and spinal fluid were obtained for determination of levels of streptomycin, and these data will be reported later.

Cultures of the spinal fluid, blood, nose and throat in beef-heart-infusion broth and agar containing added yeast extract, tryptose peptone and blood were made daily during the course of strepto-

mycin therapy and at frequent intervals after treatment was stopped. All the cultures were incubated at 37°C under increased carbon dioxide tension for at least seven days before being discarded as showing no growth. All the organisms resembling *H influenzae* morphologically were identified by the production of capsular swelling with Type B antiserum except in the cases due to a nontypable strain.

All patients treated with streptomycin were observed in the hospital for a period of at least two weeks after therapy had been stopped and were seen two to six weeks following discharge to note whether they developed any sequelae.

CASE REPORTS

CASE 1. C. W., a 5-year-old girl, was admitted to the Haynes Memorial Hospital with a chief complaint of vomiting and stiff neck of 24 hours' duration. She had been perfectly well until the evening before admission, when she began to vomit after every attempt to take food or water. A physician who was called prescribed sulfadiazine which was not retained because of the vomiting. During the night, the temperature rose to 105°F, there were slight convulsive movements and the patient complained of severe headache. On the morning of entry to the hospital the neck was stiff, the temperature was 103°F, and the patient was delirious.

Physical examination revealed the temperature to be 103°F, the pulse 140, and the respirations 22. The nose was moderately obstructed, but the mucous membrane was not inflamed. The pharynx was mildly injected, but the tonsils were not enlarged or reddened. The neck was stiff, and there was a moderate degree of cervical lymphadenopathy. The lungs, heart and abdomen were within normal limits. All the deep and superficial reflexes were present, normally active and equal on both sides. Plantar response was flexor. Kernig's sign was markedly positive bilaterally, and there was marked stiffness of the back.

The urine on admission was within normal limits. The hemoglobin was 9.3 gm, and the white-cell count 32,400, with 87 per cent neutrophils, 4 per cent lymphocytes and 9 per cent monocytes. Lumbar puncture or admission revealed an initial pressure equivalent to 160 mm of water, with free dynamics. There were 6000 cells, 98 per cent of which were polymorphonuclear leukocytes. The total protein was 250 mg per 100 cc and the sugar 26 mg. A gram stain showed long and short pleomorphic gram-negative rods, which did not swell with Type A or B anti-influenza serum. Blood culture on admission yielded the same bacterium. Subsequent bacteriologic studies revealed the organism to be *H influenzae*, belonging to neither Type A nor B.

Immediately after admission, the patient was given 3 gm of sulfadiazine per day, with resulting blood levels of 10 to 24 mg per 100 cc. On this treatment, the clinical condition improved gradually, signs of meningeal irritation lessened, and the white-cell count fell, but the temperature remained elevated. The spinal fluid during the first 2 weeks in the hospital showed a return toward normal, but the cultures remained positive for *H influenzae* for the first week and a half. Late in the 2nd week, there developed a maculopapular itching rash that was thought to be due to the sulfadiazine. No therapy was given for 3 days, during which time the temperature was elevated, the patient again appeared extremely ill, and the spinal fluid cultures grew the gram-negative organism. Sulfamerazine, in doses of 1.5 to 2.0 gm per day, was therefore given, and for a week the temperature was more or less within normal limits, but one spinal fluid examination during this time still revealed the presence of the causative bacteria. On about the 10th day of treatment, the patient began to develop a fever and a maculopapular rash, and the drug was stopped for several days, during which the temperature returned to normal. After 4 days without any chemotherapy, however, the temperature suddenly rose to 104°F and sulfamerazine was again given. For the next 3 weeks,

in spite of sulfamerazine blood levels ranging between 12 and 24 mg per 100 cc, there was a daily elevation of temperature to a high degree, and spinal-fluid and blood cultures revealed the gram-negative pleomorphic rod. The patient again appeared quite ill, had marked anorexia, was very listless and showed signs of moderate meningeal irritation. Streptomycin treatment was started at the end of the 8th week in the hospital. A dose of 5000 units was given

The patient was observed in the hospital for 3 weeks after streptomycin was stopped, and several lumbar punctures carried out during this period were all within normal limits.

CASE 2 H. M., a 3-year-old girl, was admitted to the hospital with an illness that began the day prior to admission with nasal discharge, anorexia, irritability and sensations of chilliness. Later, sore throat and pain in the side

FIGURE 1 Summary of Data in Case 1

intrathecally every twenty-four hours for the first three days and one of 10,000 units by the same route thereafter, the total dose being 255,000 units in 23 days. Shortly

of the neck developed, the respirations became labored, there was difficulty in swallowing water, and vomiting occurred. A dose of penicillin was given, and the patient was referred

FIGURE 2 Summary of Data in Case 2

after therapy with the antibiotic agent was started, the temperature returned to normal, the white-cell count fell, and the blood and spinal-fluid cultures became negative. There was a concurrent rapid improvement in the clinical condition.

to the hospital with a possible diagnosis of poliomyelitis. Physical examination on admission revealed a well developed, well nourished child who appeared acutely ill and held her head rigidly backward, resisting any attempt at flexion of the neck. The temperature was 102.8°F,

intrathecally. Most recently, Herrell and Nichols,¹² in a discussion of the clinical use of streptomycin in various conditions, have reported recovery in 4 cases of influenzal meningitis, 3 of which were due to Type B, the other being caused by an untypable strain, 2 of the patients received additional forms of treatment. The immediate results in all the cases were good, but 1 patient died two months later of a postmeningitic hydrocephalus.

The purpose of the work reported here was to determine the effect of streptomycin on the clinical course of influenzal meningitis, to study the rate of disappearance of the causative organism from the blood stream and spinal fluid and to note any toxic effects that might result from the use of large amounts of the drug.

METHODS

Streptomycin therapy was not started in any patient until the diagnosis of meningitis due to *H influenzae* was established by bacteriologic methods. In a few cases, the causative agent was detected on direct examination of the spinal fluid by the production of capsular swelling with Type B antiserum. In several cases, because of the absence of organisms in gram stains of centrifuged sediment of the spinal fluid, it was impossible to make an etiologic diagnosis until two to three days had elapsed. It was not deemed justifiable to withhold all therapy in cases in which the causative organism could not be detected early in the course of the illness, because all the patients had obvious purulent meningitis. Therefore, chemotherapy other than streptomycin was given until *H influenzae* was isolated, but a period of at least twenty-four to forty-eight hours was allowed to elapse without any type of treatment before streptomycin was given. In this way, it was hoped to avoid treating patients with more than one agent at a time. In all the cases in which treatment was withheld for twenty-four to forty-eight hours, the presence of *H influenzae* in the spinal fluid was confirmed before streptomycin was started.

Streptomycin was administered by two routes, intramuscularly and intrathecally, in a daily dosage of 120,000 to 1,000,000 units by the former route and one of 10,000 to 100,000 units by the latter. The intramuscular injections were spaced at three-hour intervals and each consisted of 15,000 to 125,000 units, whereas the intrathecal ones contained 10,000 to 100,000 units and were given once every twelve to twenty-four hours. Treatment was continued for seven to nineteen days intramuscularly and for at least four to seven days longer intrathecally. Samples of serum and spinal fluid were obtained for determination of levels of streptomycin, and these data will be reported later.

Cultures of the spinal fluid, blood, nose and throat in beef-heart-infusion broth and agar containing added yeast extract, tryptose peptone and blood were made daily during the course of strepto-

mycin therapy and at frequent intervals after treatment was stopped. All the cultures were incubated at 37°C under increased carbon dioxide tension for at least seven days before being discarded as showing no growth. All the organisms resembling *H influenzae* morphologically were identified by the production of capsular swelling with Type B antiserum except in the cases due to a nontypable strain.

All patients treated with streptomycin were observed in the hospital for a period of at least two weeks after therapy had been stopped and were seen two to six weeks following discharge to note whether they developed any sequelae.

CASE REPORTS

CASE 1. C W, a 5-year-old girl, was admitted to the Haynes Memorial Hospital with a chief complaint of vomiting and stiff neck of 24 hours' duration. She had been perfectly well until the evening before admission, when she began to vomit after every attempt to take food or water. A physician who was called prescribed sulfadiazine, which was not retained because of the vomiting. During the night, the temperature rose to 105°F, there were slight convulsive movements and the patient complained of severe headache. On the morning of entry to the hospital the neck was stiff, the temperature was 103°F, and the patient was delirious.

Physical examination revealed the temperature to be 103°F, the pulse 140, and the respirations 22. The nose was moderately obstructed, but the mucous membrane was not inflamed. The pharynx was mildly injected, but the tonsils were not enlarged or reddened. The neck was stiff, and there was a moderate degree of cervical lymphadenopathy. The lungs, heart and abdomen were within normal limits. All the deep and superficial reflexes were present, normally active and equal on both sides. Plantar response was flexor. Kernig's sign was markedly positive bilaterally, and there was marked stiffness of the back.

The urine on admission was within normal limits. The hemoglobin was 93 gm, and the white-cell count 32,400, with 87 per cent neutrophils, 4 per cent lymphocytes and 9 per cent monocytes. Lumbar puncture on admission revealed an initial pressure equivalent to 16 mm of water, with free dynamics. There were 6000 cells per cent of which were polymorphonuclear leukocytes. The total protein was 250 mg per 100 cc and the sugar 26 mg. A gram stain showed long and short pleomorphic gram-negative rods, which did not swell with Type A or B anti-influenza serum. Blood culture on admission yielded the same bacterium. Subsequent bacteriologic studies revealed the organism to be *H influenzae*, belonging to neither Type A nor B.

Immediately after admission, the patient was given 3 gm of sulfadiazine per day, with resulting blood levels of 10 to 24 mg per 100 cc. On this treatment, the clinical condition improved gradually, signs of meningeal irritation lessened, and the white-cell count fell, but the temperature remained elevated. The spinal fluid during the first 2 weeks in the hospital showed a return toward normal, but the cultures remained positive for *H influenzae* for the first week and a half. Late in the 2nd week, there developed a maculopapular itching rash that was thought to be due to the sulfadiazine. No therapy was given for 3 days, during which time the temperature was elevated, the patient again appeared extremely ill, and the spinal fluid cultures grew the gram-negative organism. Sulfamerazine, in doses of 1.5 to 2.0 gm per day, was therefore given, and for a week the temperature was more or less within normal limits, but one spinal fluid examination during this time still revealed the presence of the causative bacteria. On about the 10th day of treatment, the patient began to develop a fever and a maculopapular rash, and the drug was stopped for several days, during which the temperature returned to normal. After 4 days without any chemotherapy, however, the temperature suddenly rose to 104°F and sulfamerazine was again given. For the next 3 weeks,

were lymphocytes. The sugar was within normal limits, and the protein was 39 mg per 100 cc. No organisms were seen on smear. Since the etiology of the meningitis was unknown the patient was treated with 1.5 gm of sulfadiazine a day. Lumbar puncture repeated the next day showed essentially the same findings as on the day before.

On the 4th day, the cultures of the spinal fluid made on the 2nd and 3rd days were found to contain Type B *H. influenzae*. Sulfadiazine administration was stopped, and the patient was given no treatment for 24 hours. Streptomycin therapy, 125,000 units every 3 hours intramuscularly and 25,000 units every 24 hours intrathecally, was started and continued for 9 days by the former and for 3 days longer by the latter route.

There was rapid clinical improvement, and the abnormalities in the spinal fluid soon disappeared. *H. influenzae* was never isolated from the nose, throat or blood.

CASE 4 W. S. L., a 3-year-old boy, was admitted with a chief complaint of convulsions of 24 hours' duration. One week prior to admission he had sustained a contusion on the back of the head as the result of a fall, and subsequently developed fever, nausea, vomiting and abdominal pain. He was treated for the next 5 days for gastroenteritis.

424 lymphocytes per cubic millimeter. The sugar was 59 mg per 100 cc, and the protein 87 mg, but no bacteria were seen on direct examination of a centrifuged specimen. Nose, throat and blood cultures revealed no *H. influenzae*. Cultures of the spinal fluid showed no growth after 24 and 48 hours. Because of the obvious purulent meningitis and the failure to discover the causative organism at the time of admission, the patient was given 3 gm of sulfadiazine a day. On this regimen the temperature remained elevated, the patient continued to appear acutely ill and opisthotonos persisted.

On the 4th day, because growth of the spinal-fluid cultures could not be detected by the ordinary methods, the supernatant was removed from the blood broth and centrifuged at 3000 r.p.m. for 30 minutes. Examination of the sediment revealed that *H. influenzae*, Type B, had been present in the spinal fluid from the time of admission. All therapy was omitted for the next 24 hours, during which time the temperature rose to its highest point 103°F. On the 6th day, when the white-cell count was 31,000 and the temperature 103.8°F, treatment with streptomycin was begun. A dose of 100,000 units was administered intrathecally initially and doses of 25,000 units were given every 24 hours thereafter for 14 days. In addition a dose

DEC. 13, 1945

FIGURE 4 Summary of Data in Case 4

but because vomiting and convulsions occurred 5 days after the fall, he was admitted to an outlying hospital for observation. Physical examination at that time revealed the patient to be acutely ill and in poor contact with his surroundings. The only neurologic finding was a moderate degree of opisthotonos. Twenty-four hours later, marked restlessness and delirium appeared and lumbar puncture yielded a reddish-colored spinal fluid under markedly increased pressure. Penicillin intrathecally and intramuscularly and sulfadiazine produced no improvement in 24 hours, and the patient was referred to this hospital.

Physical examination on admission revealed a well-nourished, well-developed boy who was in marked opisthotonos, restless and irritable and appeared extremely ill. The temperature was 100.6°F, the respirations 24, and the pulse 152. The mouth was dry, and the tongue coated. The neck and back were markedly stiff, with the head held in extreme extension, and the patient protested violently against any attempt at flexion. Kernig's sign was markedly positive bilaterally. The abdominal reflex in the left lower quadrant could not be elicited. The remainder of the examination was normal.

The urine on admission was within normal limits. The hemoglobin was 14.1 gm. The white-cell count was 22,900, with 72 per cent neutrophils, 26 per cent lymphocytes and 2 per cent monocytes. Lumbar puncture yielded a spinal fluid that contained 543 polymorphonuclear leukocytes and

of 125,000 units was injected every 3 hours intramuscularly for 10 days.

Shortly after the beginning of streptomycin therapy marked improvement in the clinical course was noted, and the patient was completely recovered 15 days after treatment was begun. Spinal-fluid cultures became negative 2 days after streptomycin was given, and the chemical and cellular abnormalities of the fluid rapidly disappeared. Numerous blood cultures made during the course of the disease were sterile.

CASE 5 S. A., a 15-month-old girl, was admitted with a chief complaint of convulsions of 12 hours' duration. One week prior to admission, the patient developed a "cold" which was quite mild for the first few days but was followed by diarrhea consisting of several loose, nonbloody stools a day until 24 hours before entry. The next morning, the patient was irritable, refused to sit up and developed generalized twitchings. On admission to an outlying hospital, she was found to have a stiff back and neck, a temperature of 102°F, and a positive Kernig's sign bilaterally. The white-cell count was 19,500, and lumbar puncture yielded a spinal fluid that contained 4500 cells per cubic millimeter. Penicillin was immediately given intrathecally and intramuscularly, but when bacteriologic examination of the spinal fluid several hours later revealed Type B *H. influenzae* anti-influenza serum was administered in doses of

the pulse 120, and the respirations 26. On the right side of the neck, behind the right mandibular angle, there was a small, hard, tender swelling that was surrounded by edema. There was enlargement of the tonsillar node on the left. The remainder of the physical examination was within normal limits. Kernig's sign was negative bilaterally, and stiffness of the back was not striking.

The white-cell count was 17,500, with 64 per cent neutrophils, 32 per cent lymphocytes and 4 per cent monocytes. The urine was essentially normal. The spinal fluid was under normal pressure and contained 10 lymphocytes and 6 polymorphonuclear leukocytes per cubic millimeter, the sugar and protein levels were normal and culture yielded no growth.

Shortly after admission the temperature rose to 105°F, and a dose of 15,000 units of penicillin was given intramuscularly every 3 hours. At the end of 18 hours, the temperature had decreased to 100.8°F, but it fluctuated between

consistent with early bronchopneumonia. *H. influenzae* was isolated from nose and throat cultures for the first time on the 21st day. At discharge 34 days after admission, the patient showed no sequelae except moderate generalized weakness.

CASE 3. L. A., a 2-year-old girl, was admitted with an illness that had begun 3 weeks previously, with mild obstruction of the nose and a high degree of fever. Because of the finding of moist rales in one of the lungs, treatment with one of the sulfonamides had been given for 4 days. Thereafter, fever recurred and the sulfonamide was readministered, but failed to produce any beneficial results. The patient was therefore admitted to a hospital for further study 4 days prior to admission to this hospital.

At the outlying hospital a large number of white cells were found in the urine. Treatment with penicillin resulted in some improvement. On the night before admission

FIGURE 3 Summary of Data in Case 3

101 and 105° for the next 3 days. On the 4th day, marked stiffness of the neck, back and hamstring muscles and positive Kernig signs became evident. The spinal fluid was under increased pressure and contained 1100 white cells per cubic millimeter, with 82 per cent polymorphonuclear leukocytes and 18 per cent lymphocytes. The sugar level was 21 mg per 100 cc and the protein level 63 mg. Type B *H. influenzae* was identified on direct examination.

Penicillin was stopped and a regimen of 25,000 units of streptomycin intrathecally once every 24 hours and 125,000 units of streptomycin intramuscularly every 3 hours was instituted. The temperature fell rapidly and by the 8th day had reached normal limits, where it remained during the rest of the hospital stay. The cell count in the spinal fluid gradually decreased, and the cultures for *H. influenzae*, which were twice positive during the first 3 days of streptomycin treatment, became negative on the 4th day and remained so thereafter. There was marked improvement in the patient's clinical condition, and all signs of meningeal irritation had disappeared at the end of 6 days of streptomycin treatment. The drug was continued both intramuscularly and intrathecally for 10 days, and by the latter route alone for 6 days longer.

The white-cell count, which fell to 4000 on the 2nd day, rose to 28,000 on the 10th day and returned to a normal level on the 16th day, where it remained for the rest of the period of observation. Blood cultures were positive for *H. influenzae* on the 1st, 3rd, 4th, and 6th days only once after the start of streptomycin treatment. X-ray examination of the chest on the 5th day revealed findings

to this hospital, stiffness of the neck and a rise in temperature to 103°F developed. Lumbar puncture yielded a clear fluid under increased pressure. The patient was transferred to another hospital with the diagnoses of pyelonephritis and meningitis, type undetermined, having received 25,000 units of penicillin and 2 gm of sulfadiazine just before discharge. At the second hospital, a rash was noted and the patient was sent to this hospital with a possible diagnosis of scarlet fever.

Physical examination on admission revealed a pale girl who appeared to be chronically ill. The temperature was 100.4°F, the pulse 128, and the respirations 28. The skin showed a moderate degree of hyperkeratosis follicularis over the chest and abdomen. The remainder of the examination was within normal limits except for a few moderately enlarged anterior cervical lymph nodes. There were no signs of meningeal irritation or increased intracranial pressure except for slight tightness of the hamstring muscles bilaterally. The remainder of the neurologic findings were essentially normal.

The white-cell count on admission was 22,150, with 55 per cent neutrophils, 45 per cent lymphocytes and 1 per cent monocytes. The urine was normal except for 5 to 10 white cells per high-power field of a centrifuged specimen. Shortly after admission, the temperature rose to 102.4°F and slight stiffness of the neck and increased spasm of the hamstring muscles became apparent. Lumbar puncture revealed increased pressure of the spinal fluid, which contained 389 cells per cubic millimeter of which 54 per cent were polymorphonuclear cells and 44 per cent

could be cultured. All blood and spinal-fluid cultures made during the time of streptomycin treatment and after the antibiotic substance was stopped were sterile. The patient was kept in the hospital for 4 weeks following the completion of treatment and remained completely well.

CASE 6 H M, a 3-year-old boy, entered the hospital with a chief complaint of fever and vomiting of 12 hours' duration. He had been well until 4 days prior to admission, when he began to suffer with poorly described discomfort in the left ear. No other symptoms appeared until the day before admission, when severe anorexia, fever, restlessness, increased irritability and vomiting were present. A physician who saw the patient on the following day found him to have a temperature of 103°F and a stiff neck and referred him to the hospital.

Physical examination on admission revealed a well developed, well nourished boy who was comatose and responded only to extremely painful stimuli. The temperature was 102°F, the respirations 36, the pulse 124, and

drug was administered intramuscularly every 3 hours in doses of 100,000 units for 10 days and intrathecally every twenty-four hours in doses of 25,000 units for 14 days.

The clinical course was marked by rapid improvement, so that within 1 week the patient appeared to be completely recovered. A rise in temperature to 102°F on the 21st day occurred, with an acute suppurative otitis media, from which a hemolytic *Staphylococcus aureus* but not *H. influenzae* was isolated. This condition subsided without any treatment in a few days. After therapy was started, cultures of the blood were never positive and those of the spinal fluid revealed the causative organism only once. Daily cultures of the nose and throat revealed Type B *H. influenzae* — for the first time on the 29th and 30th days.

CASE 7 W V, a 4-month-old boy, was admitted because of convulsions of 24 hours' duration. The present illness began 10 days prior to admission, when the patient

FIGURE 7 Summary of Data in Case 7

the blood pressure 75/40. In the skin over the medial aspect of the lower left leg were several small, edematous, papular areas, the tops of which were crusted. The left ear drum was diffusely reddened, but the landmarks could be made out easily. The eyes moved aimlessly. The pharynx and tonsils were markedly reddened but no exudate was seen. The neck and back were extremely stiff. Neurologic examination was essentially negative except for absent abdominal reflexes and a strongly positive Kernig's sign bilaterally.

The urine on admission was entirely within normal limits. The hemoglobin was 16.2 gm. The white-cell count was 7950, with 79 per cent neutrophils, 16 per cent lymphocytes and 5 per cent monocytes. Lumbar puncture on admission revealed an initial pressure equivalent to 480 mm. of water, with normal dynamics, and the spinal fluid contained 3650 cells, 99 per cent of which were polymorphonuclear leukocytes. The protein was 250 mg. per 100 cc., and the sugar 54 mg. A gram stain showed pleomorphic gram-negative rods that proved to be Type B *H. influenzae* both by direct typing and by culture. Blood cultures yielded the same organism.

Because of an error in the bacteriologic diagnosis on the original examination of the spinal fluid, the patient was given 15 gm. of sulfamerazine intravenously. When the presence of *H. influenzae* was detected 1 hour later, streptomycin, 50,000 units intrathecally and 100,000 units intramuscularly, was given immediately. Thereafter, the

developed a mild upper respiratory infection, which had an uneventful course until the 4th day, when the temperature rose to 103°F. The patient did not appear particularly ill, but on the next day the temperature was 104°F. Examination by a physician at that time revealed nothing of note, and treatment with an antipyretic led to a fall in temperature to 100°F for 24 hours. The next day the temperature was 103°F and the patient was given one of the sulfonamide drugs; this produced a moderate degree of improvement. On the day before admission, the patient began to have generalized convulsive seizures, which rapidly increased in frequency and duration until they were present almost constantly at the time of entry to an outlying hospital, where a lumbar puncture revealed cloudy spinal fluid containing gram-negative pleomorphic bacteria. Because of this finding, the child was referred to this hospital for treatment.

On admission the patient was a well developed, moderately obese infant who held himself rigid, with all the extremities in flexion and the head in extension. The temperature was 102.2°F, the respirations 32, and the pulse 130. The anterior fontanelle was wide open and bulging. The lower part of the right tympanic membrane was red, and the light reflex and visibility of the bony landmarks were diminished. The eyes followed a bright light to the right but not to the left. The nose contained a small amount of purulent exudate, and the mucous membrane was reddened. The pharynx was slightly reddened.

5 cc intravenously and 6 cc intrathecally. The patient was referred to this hospital for further treatment.

Physical examination on admission revealed a well developed, well nourished child who was pale and irritable, breathed rapidly with grunting respirations and stared vacantly into space. The temperature was 104°F, the pulse 180, and the respirations 60. The left eardrum appeared thick and injected. The nose revealed a small amount of mucopurulent exudate. The pharynx was

Because of the rapid fall in temperature and the general clinical improvement, as well as the negative blood and spinal-fluid cultures, all therapy was withheld for the first 3 days. At the end of this time, spinal fluid withdrawn on the 2nd day was found to contain *H. influenzae*, sulfadiazine, 3 gm per day orally, was therefore started. Lumbar punctures on the 8th, 10th, 12th and 13th days made while the patient was receiving sulfadiazine, revealed *H. influenzae*. All therapy was then stopped for 48 hours.

FIGURE 5 Summary of Data in Case 5

moderately injected, the tonsils were slightly enlarged, and a thick, purulent postnasal discharge was present. The neck and back were moderately stiff. The neurologic findings were within normal limits except for a slightly positive Kernig's sign bilaterally. The remainder of the examination revealed no abnormalities.

The white-cell count on admission was 16,850, with 45 per cent neutrophils, 52 per cent lymphocytes and 3 per cent monocytes. The urine was within normal limits

during which time the temperature rapidly rose to fluctuate between 99 and 103°F. The patient again appeared acutely ill, and blood and spinal-fluid cultures grew out the hemophilic bacteria.

Streptomycin, 25,000 units intrathecally every 24 hours and 125,000 units intramuscularly every 3 hours, was first administered on the 16th day and was continued for 8 days by the latter route and for an additional 6 days by the former route. Within a short time after the initiation of

FIGURE 6 Summary of Data in Case 6

except for a specific gravity of 1.032. The hemoglobin was 11.6 gm. Examination of the spinal fluid revealed 165 polymorphonuclear leukocytes, 3000 lymphocytes and 5000 erythrocytes per cubic millimeter, the protein was 252 mg per 100 cc, and the sugar 65 mg. Gram stains and cultures of the spinal fluid on admission were negative for *H. influenzae* or any other organism.

this treatment, the temperature returned to within normal limits and marked improvement in the general clinical condition was noted. The spinal fluid showed a rapid return to normal. A mild elevation of temperature from the 27th through the 30th day was concomitant with a bout of diarrhea consisting of several loose, nonbloody stools a day, from which no pathogenic enteric organisms

to twelve green, watery stools a day, had been present. Four days before entry, the patient had a "cold" and showed difficulty in swallowing. During the next few days, she became drowsy, and just before admission began to have twitchings of the right side of the head and frothed at the mouth.

Physical examination revealed a pale, emaciated girl who held her eyes wide open and her neck in slight extension. The temperature was 101°F, the pulse 150, and the respirations 30. The arms and legs were semirigid and flexed. There was marked looseness of the skin over the whole body. There was a small amount of purulent exudate in the nose. The neck and back were stiff. The lungs were clear except for coarse rhonchi throughout. All reflexes were physiologic. There was a thick, purulent vaginal discharge. The remainder of the physical examination was within normal limits.

The white-cell count on admission was 25,000. The urine was normal except for a large number of white cells. The hemoglobin was 9.3 gm. A lumbar puncture revealed increased pressure, and the fluid contained 910 cells per cubic millimeter, 80 per cent of which were polymorphonuclear leukocytes. The total protein was 95 mg per 100 cc, and the sugar 34 mg. Direct examination revealed gram-negative pleomorphic rods resembling *H. influenzae* but not typable with either Type A or B serum. Culture of the vaginal discharge yielded *Proteus vulgaris* and colon bacilli. The blood was sterile. An untypable strain of *H. influenzae* was isolated from the pharynx.

Immediately after admission, the patient was started on a regimen of 100,000 units of streptomycin intramuscularly every three hours and was given 50,000 units of the same agent intrathecally. Intramuscular therapy was con-

On the 9th day, the rectal temperature dropped to 95°F and the patient died, respirations ceasing 10 minutes before the heart stopped.

Autopsy There was hydrocephalus with marked destruction of brain tissue and many areas of fibrin, particularly about the base, from which a nontypable *H. influenzae* was isolated.

The strain of *H. influenzae* isolated from the patient was subsequently found to be susceptible to 1.25 units of streptomycin per cubic centimeter (cup method, with the Merck strain of *Staph. aureus* as the control). Concentrations of streptomycin considerably larger than this were presumably present in the spinal fluid at all times.

DISCUSSION

Nine cases of acute purulent meningitis due to *H. influenzae* were treated with streptomycin, with good results in 7 cases. In 7 cases the organisms belonged to Type B, whereas in the other 2 the bacteria were neither Type A nor B. Bacteremia was present in 7 cases at the time the meningitis was first diagnosed. The age of the patients infected with the Type B organisms varied from four months to three years, whereas the children from whom the nontypable strains were recovered were four months and five years old, respectively.

Two of the patients died. One, aged ten months, was infected with a Type B organism that disappeared from the spinal fluid and blood after twenty-four hours of streptomycin treatment. This patient subsequently developed a *Staph. aureus* bronchopneumonia and succumbed in spite of intensive penicillin therapy. At autopsy the brain revealed only two small plaques of fibrin on the cerebral hemispheres, cultures were sterile. The other patient succumbed to persistent influenza bacteria infection, which showed no response to treatment with large amounts of streptomycin. *H. influenzae*, type unknown, was cultured from the brain at autopsy.

It was the purpose of the work reported herein to determine the value of streptomycin alone in the treatment of influenzal meningitis. In every case in which prior treatment with sulfonamide or other agents had been given, a period of twenty-four to forty-eight hours without therapy of any type was therefore allowed to elapse before streptomycin was administered, to eliminate the possibility of treating with two agents at the same time and also to assure the presence of active, progressing infection. It is problematical whether prior treatment with sulfadiazine had any favorable influence on the later effectiveness of streptomycin. It is noteworthy that, in every case in which the sulfonamide was used, organisms were constantly present in the spinal fluid in spite of adequate blood concentrations of the drug. In some of the cases, however, there was some degree of clinical improvement during the period of sulfadiazine therapy. This may indicate that the infection of the meninges had been partially inhibited but not eradicated by the administration of sulfonamide, this possibility is borne out by the fact that omission of all therapy

FIGURE 9 Summary of Data in Case 9

tinned for 8 days. After the initial intraspinal dose, a dose of 25,000 units was given every 24 hours for 3 days and one of 50,000 units every 12 hours for the remaining 2½ days.

The patient rapidly lapsed into coma, showed generalized twitchings and convulsions almost constantly and had persistent fever. The white-cell count remained high. Spinal-fluid cultures revealed the presence of *H. influenzae* on each of twelve examinations carried out over a period of 8 days. Cultures of the blood were repeatedly negative.

but otherwise normal. The neck and back were extremely rigid. Kernig's sign was markedly positive bilaterally. The examination was otherwise within normal limits.

The urine on admission was normal except for a slight amount of albumin. The white-cell count was 8500, with 46 per cent neutrophils, 49 per cent lymphocytes, 3 per cent monocytes and 2 per cent basophils. The hemoglobin was 11 gm. The spinal fluid was under increased pressure and contained 36,400 cells per cubic millimeter, 91 per cent of which were polymorphonuclear leukocytes. The sugar was 30 mg per 100 cc, and the protein 50 mg. Many gram-negative pleomorphic rods that exhibited capsular swelling with Type B anti-influenza serum were present. Cultures of the spinal fluid, blood and nose were positive for Type B *H. influenzae*. This organism could not be demonstrated in the pharynx.

Immediately after the etiology of the meningitis had been established, a dose of 20,000 units of streptomycin was administered intrathecally. Twenty-four hours later, drug administration by the intramuscular route in doses of 50,000 units every 3 hours was also started. Therapy was continued by intramuscular injection for eight days and intrathecally for 5 additional days. During the 2nd, 3rd and 4th days, because of failure to improve clinically, intraspinal injections of 20,000 units of streptomycin were given every twelve hours. The spinal fluid and blood cultures became negative for *H. influenzae* within 24 hours after therapy was instituted. The convulsions, twitchings, stiff neck and positive Kernig's sign disappeared after 11 days of treatment.

On the 8th day, the temperature rose to 104.6°F. Blood and spinal fluid cultures, which had been made daily, showed a coagulase-positive hemolytic *Staph. aureus* continually from the 7th day onward, but because the organisms grew very slowly and the first three cultures were considered to be possible contaminants, the diagnosis of staphylococcal meningitis and bacteremia was not made until 1 week after onset. *Staph. aureus* was present in the nose in pure culture on the 8th day. In spite of the new infection of the meninges, the clinical condition was improving rapidly except for the appearance of a scarlatiniform rash over the entire body from the 10th to the 12th day.

Because spinal-fluid and blood cultures were persistently positive for *Staph. aureus*, penicillin was given intrathecally, 25,000 units every 24 hours, and intramuscularly, 15,000 units every 3 hours, for the first 8 days, when the amount administered by each route was doubled because spinal-fluid and blood cultures still revealed the causative organism. Following the increase in dose of the antibiotic agent, these cultures rapidly became negative.

A febrile episode on the 26th day was probably related to an upper-respiratory infection, since redness of the pharynx and a watery nasal discharge were present at this time.

Type B *H. influenzae* was isolated from the throat in pure culture several times after recovery from the influenzal meningitis. The patient was observed in the hospital for 2 weeks following the cessation of penicillin treatment and showed no residua or sequelae of the meningeal infections. This part of the course of the illness is not included in Figure 7.

CASE 8 C G, a 10-month-old girl, became ill 2 days prior to admission, when she cried much more than normally and became quite drowsy. On the day before entry, she began to vomit, appeared pale, was quite warm and slept almost constantly. Later in the day, when stiffness of the neck and a temperature of 103°F were noted, the patient was referred to this hospital.

Physical examination revealed a well developed, well nourished girl who was extremely restless, breathed rapidly and emitted frequent high-pitched cries. The temperature was 105.6°F, the pulse 150, and the respirations 44. She reacted readily to painful stimuli. The anterior fontanelle was normal. There was an internal strabismus of both eyes. The neck and back were stiff. Kernig's sign was negative. There was a small area of consolidation in the midportion of the right lung posteriorly. The remainder of the physical examination was within normal limits.

The white-cell count on admission was 10,850, with 70 per cent neutrophils, 29 per cent lymphocytes and 1 per cent monocytes. The hemoglobin was 12.3 gm. The spinal

fluid was under increased pressure and contained 18,250 cells per cubic millimeter, 80 per cent of which were polymorphonuclear leukocytes. The protein was 114 mg per 100 cc, and the sugar 26 mg. Direct examination revealed gram-negative pleomorphic rods that gave capsular swelling with Type B anti-influenza serum. The blood culture revealed Type B *H. influenzae*. Nose and throat cultures were negative for *H. influenzae*.

Treatment with streptomycin was started immediately after admission. A dose of 100,000 units was given intr

FIGURE 8 Summary of Data in Case 8

muscularly every 3 hours for 5½ days. After a period of 2 days with no treatment, the drug was again given and 1,200,000 units was administered in the next 30 hours. Fifty thousand units of the antibiotic agent was instilled into the spinal canal on admission, and 25,000 units was given every 24 hours thereafter for the next 10 days.

The blood and spinal-fluid cultures revealed no organisms 24 hours after the beginning of treatment, and none were recovered during the remainder of the course. The clinical condition improved somewhat in that the temperature reached a normal level on the 5th day, but coma and twitchings persisted. On the 5th day, a pure culture of *Staph. aureus* appeared in the nose and throat, and this organism was isolated every day thereafter. On the 8th day, the temperature suddenly rose to 102°F, and it remained at high levels for the rest of the course. Physical examination at that time revealed no abnormalities, but on the following day moist, crackling rales were heard throughout both lung fields and x-ray examination revealed diffuse bilateral bronchopneumonia. Since it was thought that this was probably due to *Staph. aureus*, the patient was treated with penicillin, 15,000 units being given intramuscularly every 3 hours for the next 4 days. The patient remained in coma, convulsions became more frequent and severe, the temperature continued to be elevated, and death occurred on the 12th day. Blood cultures grew out *Staph. aureus* during the last two days of life.

Autopsy The brain was within normal limits except for two small plaques of fibrin, one on each of the cerebral hemispheres, bacteriologic studies were negative. The lungs showed a diffuse confluent bronchopneumonia from which a coagulase-positive hemolytic *Staph. aureus* was isolated.

CASE 9 K B, a 4-month-old-girl, was admitted with a history of having had a bronchopneumonia, which responded to one of the sulfonamides, 2 weeks previously. For 1 week before admission, diarrhea, consisting of seven

SUMMARY AND CONCLUSIONS

Nine cases of purulent meningitis due to Type B *Haemophilus influenzae* in 7 and to an untypable strain in 2, were treated with streptomycin, with complete recovery in 7 cases. The drug was given intramuscularly in doses ranging from 15,000 to 125,000 units every three hours and intrathecally in amounts varying from 10,000 to 25,000 units every twenty-four hours.

Two of the 9 patients with influenzal meningitis treated with streptomycin died. One showed complete absence of response to the antibiotic agent. The other died of an intercurrent *Staphylococcus aureus* bronchopneumonia, which was not affected by penicillin.

The blood and spinal fluid were cleared of the causative organisms in twenty-four to forty-eight hours in all cases except the 2 due to atypical strains.

No relapses or sequelae of the influenzal meningitis were observed in any of the recovered patients over a period of six to ten weeks following the cessation of streptomycin treatment.

No toxic reactions attributable to streptomycin were observed in the nervous, hematopoietic or urinary systems.

Two of the patients receiving streptomycin developed infections, in one case meningitis and in the other bronchopneumonia, — both with bacteremia, — due to *Staph aureus* after they were completely free of *H influenzae* in both the spinal fluid and blood for several days and were apparently recovering clinically.

Since *Staph aureus* infections may occur as complications during treatment with streptomycin, careful watch must be maintained for early signs of this type of involvement. The use of penicillin as soon as *Staph aureus* becomes the predominant organism in the nasopharynx, even before the evidence of invasion is present, is strongly recom-

mended. The possibility of administering penicillin and streptomycin together from the time treatment is started suggests itself.

Streptomycin appears to be the drug of choice in the treatment of meningitis due to *H influenzae*. It should be administered by both intrathecal and intramuscular routes. There seems to be no need to combine the antibiotic agent with one of the sulfonamides or with type-specific antiserum unless no beneficial effects result from the use of large amounts of streptomycin given for at least seventy-two to ninety-six hours.

Addendum Another patient with meningitis due to Type B *H influenzae* has recently been treated with streptomycin. This four-year-old boy recovered after treatment for six days by the intramuscular and ten days by the intrathecal route, the causative organism disappearing from the cerebrospinal fluid in less than twenty-four hours. Recovery was complete and no sequelae were evident six weeks after discharge from the hospital.

rapidly produced increased severity of clinical manifestations, bacteremia and an increase in the abnormal changes in the spinal fluid

The portal of entry for *H influenzae* infection in most cases appeared to be the upper respiratory tract. In 2 cases, otitis media was present, in neither of these, however, were the gram-negative bacteria isolated from the ear. In 6 cases *H influenzae* was isolated from the pharynx and nose. It is interesting that in 2 of these cases the organisms could not be recovered until after the patients had been treated with streptomycin and were recovering from the meningitis.

The dosage and time of administration of streptomycin were chosen more or less arbitrarily. In Case 1, relatively small amounts of the drug were injected because only little of the material was available. In the other 8 patients between 800,000 and 1,000,000 units was given daily in divided intramuscular doses every three hours. Every patient received, in addition, between 20,000 and 100,000 units of the drug intrathecally because, as has been shown by Anderson and Jewell,¹³ streptomycin does not enter the spinal fluid in appreciable amounts when injected either intramuscularly or intravenously. The usual procedure was to give 50,000 or 100,000 units intrathecally when treatment was first started and to instill 25,000 units every twenty-four hours thereafter. In two cases, it was considered necessary to give the drug more frequently by the intrathecal route, in these cases it was administered every twelve hours for several days. The total dosage of streptomycin for the entire period of treatment varied between 2,725,000 and 9,500,000 units intramuscularly and 225,000 and 475,000 units intrathecally. Whether the quantity of streptomycin used in the cases reported was larger than that actually necessary to cure influenzal meningitis can be determined only from experience with the use of smaller doses. The possibility of administering the antibiotic agent by the intrathecal route alone in cases of meningitis due to *H influenzae* suggests itself, but such a procedure appears too risky, because about 70 per cent of patients with this disease have concurrent bacteremia. Reduction of the length of time over which intramuscular therapy is given seems more feasible because, in most cases, the blood was found to be sterile after twenty-four to forty-eight hours of treatment.

In most cases, the rapidity with which both spinal fluid and blood were rid of *H influenzae* following the administration of streptomycin is extremely striking. Of the 8 patients treated with large doses, the spinal fluid was free of the hemophilic bacteria in 2 cases in less than twenty-four hours and in 5 between twenty-four and forty-eight hours. In 1 case, the organisms never disappeared. In the patient given relatively small doses of the

drug, ninety-six hours was required before sterilization of the spinal fluid was accomplished. Disappearance of the infecting organisms from the blood stream was even more rapid than that from the spinal fluid. In only 1 case was bacteremia still present twenty-four hours after the beginning of treatment, in all the others the blood was free of bacteria in less than twenty-four hours. The fact that large amounts of streptomycin do not prevent the establishment of a new infection by an organism not susceptible to the drug is illustrated by the 2 patients who developed *Staph aureus* meningitis and bronchopneumonia with bacteremia while undergoing treatment for the *H influenzae* infection. No toxic effects directly related to streptomycin were observed.

The development of severe infections with *Staph aureus* in 2 cases is worthy of note. It is striking that in both these cases the organisms appeared in pure culture in the nasopharynx before they invaded more deeply. It is possible that streptomycin, by altering the relation of the various organisms in the pharynx, may, in some situations, allow relatively insusceptible organisms like *Staph aureus* to increase rapidly in numbers and virulence. The use of penicillin in combination with streptomycin for the treatment of gram-negative infections suggests itself as a possible procedure in avoiding late complications by infection with gram-positive organisms. The necessity for careful frequent study of the nasopharyngeal bacterial flora in patients being treated with streptomycin seems apparent, and the use of penicillin when many gram-positive pathogenic organisms such as *Staph aureus* make their appearance, in an attempt to prevent invasion by these bacteria, seems strongly indicated.

All the recovered cases treated with streptomycin were observed on the wards for two to four weeks following cessation of therapy, and in no case were sequelae of the infection or the treatment observed. Several of the patients were in good health two to six weeks after leaving the hospital.

Although the number of patients treated is small, the present study indicates that, in most cases, streptomycin is an effective agent in the treatment of meningitis and bacteremia due to *H influenzae*. The results obtained compare favorably with those following the use of type-specific antiserum and sulfadiazine. The employment of streptomycin in cases of *H influenzae* infections obviates any danger inherent in serum therapy and eliminates the necessity for frequent titrations to demonstrate excess antibody levels. It also precludes the occurrence of toxic reactions that may result from sulfadiazine. So far as can be determined, streptomycin is without appreciable toxic effect in man. When available in sufficient quantities, it seems to be the drug of choice in the treatment of disease produced by *H influenzae*.

We want to put in a good word for the corporals. They are willing to co-operate and are helpful. They are a swell bunch of guys. We are leaving this morning and we thought we should let them know we appreciate all the kindness we received from them — and we also enjoyed your talks.

Is this publicity on the awful conditions in veterans' hospitals true, and if not why do they print such stuff?

Dear Doctor I am a single man and I am deeply in love with a lovely lady back home. Doctor, I am getting up in age. I have had intercourse with this girl several times, and have never been able to satisfy her although we have tried again and again, but yet she still wants to marry me. Do you think it would be possible for us to have a happy married life?

Doctor Would you try to clear this question for me. During the night I wake up a few times and each time when I awaken it takes me a good ten to thirty seconds to remember where I am at. When I am trying to remember where I am at it's like a nightmare.

Dear Doctor At the present time I'm reading *A Tree Grows in Brooklyn* and I was quite surprised when the author states that several of the women characters loathed the thought of sleeping with their husbands. I have been married several years and this came as quite a shock to me. Is this common in married life? Why do women stay with their husbands if they feel this way? The only thing I find wrong with your talks is the fact that they are not nearly long enough. I would like to sign this but don't want to be accused of "ear hanging" so I'll just sign — "a patient, a fan and I feel as though I can say, a friend."

I have a problem which concerns myself as well as many others. This problem is of intermarriage. I am privately engaged to a Protestant girl and I am Jewish. I do love her very much, and vice versa. We are really in love, doctor, and the only thing preventing me from taking her hand in marriage is the matter of our children. Her father is dead, but her mother is living and my folks are living. I do love her and after being away twenty-eight months I want to marry her. Please give us some help and suggest a way to bring up the children which would be easy for all concerned. We both believe in God and because we were born to different faiths shouldn't prevent us from marriage. What religion should we teach the children? Thank you in advance. Please give us assistance.

Dear Doctor Is it possible for a homosexual person to control his emotions and lead an ordinary sex life or is he in that state mostly because he prefers to be? Is it true that intercourse after pregnancy can cause a person to be "homo" or are our reactions, likes and dislikes the reasons for homosexuality? Can a doctor help a person who sincerely wants to be helped, and what is the remedy?

Doctor, I have had a tachycardiac condition for the past year. My diagnosis is psychoneurosis anxiety. I would like to know how these two things are related and what I can do consciously to cure this ailment. During this year overexertion, excitement and stimulants have been the causes for recurrences of this heart condition. Should I leave these things alone or will each, in a proper amount, help me to effect a cure?

Dear Doctor My wife has confessed to me that she has gone out with another man during my absence. She says that it was nothing serious, but for a couple of months her letters were cool and distant, although she did write practically every day. She says now she is sorry it ever happened and that she has learned her lesson. She now claims to love me more than ever. Would you speak to her of her "going out" upon returning home, or just forget about it and try to make the best of it? I love her very much.

Doctor I have been in a melancholy state of mind for a year. What part does it play on the brain?

What makes you dream of killing people in your sleep? Is it because you hate someone very much? It always concerns me, and it wakes me up. It scares me an awful lot.

Dreams cause me to awaken with a tired and inner tumbling feeling. What can one do to suppress them? What is the nature and interpretation of a dream? Certain foods seem to be a cause, is that a foundation of fact, or a misconception?

Do worry and nervousness cause ulcers? Does continual irritation of ulcers develop into cancer? Is watch-

ing your diet the only way of healing ulcers? Does stomach trouble cause backaches?

Will you please tell us more about a hysteria neurosis — how it differs from other types of neurosis, why it is harder to overcome and whether it is acquired or hereditary?

At the morning talks I think we should talk about our future problems and what we will do when we are out of the Service instead of talking about women all the time. A lot of us are married and we don't believe our wives are running around, but drops of water on a stone will soon wear a hole.

Doctor Best of luck and an early "gettin' home" to you and your staff. You have all shown a kindness and courtesy which is a credit to the Medical Corps and yourselves. The human treatment and the chance to express themselves openly or in the "gripe box" is as democratic as any procedure I have seen in the Navy. More power to you and your practice.

Dear Doctor As you know, we had a talk on having food in the diet kitchen. The gripe before was about chiefs [chief petty officers] and corporals' eating steaks in the diet kitchen. Our gripe is who in the hell stole our two hot dogs from the refrigerator after we went through a lot of trouble swiping these dogs from the mess hall? As we are heavy eaters we have to have our snack before hitting the sack. Please inform the thief to keep his hands off our chow.

Dear Doctor Tonite is my last nite here at the hospital or I should say school. Because it's been like a school to me. You've helped me a great deal since I've been a [pupil] here, not a patient. You've learned me a great deal about life that I never before knew. By your talks every morning and your smiles that you gave us all every morning at sick call and wherever you meet us. And believe me, Doctor, that smile did me more good than all the medicine anyone could give. I knew at times it was hard to smile, but nevertheless you did. I only hope that the fellows that may enter your school gain as much out of your talks as I have. God bless you always! Keep them smiling, Doctor!

RESULTS

The following objective indications that the patients as a whole have derived considerable benefit from the program form the reason for presenting this article, as well as for continuing the talks.

Daily attendance has averaged 74 per cent. Even after the patients have been transferred to other wards because of crowding, many of them continue to return for the talks. Requests from patients on neighboring wards for permission to attend are frequently received.

At the close of the first week, the patients themselves requested a change of title for the "gripe box" on the ground that after the second day it ceased to contain any gripes. They have now adorned it with the following legends:

Worried? Curious? Troubled? Family trouble? "Dear John" letters? Leave a note for the doctor. Do you have a complaint or question you would like discussed? If so drop a note without your signature. Your medical officer will be glad to discuss any of these with the group each morning.

An unprecedented avalanche of requests for social service and legal assistance with personal problems descended on the local Red Cross department. These questions included illness and hardship at home, delayed news, financial problems and so forth. There was a sharp decrease in the number and frequency of requests to ward nurses and corporals for information — requests that often so dis-

NEW EXPERIENCES IN GROUP PSYCHOTHERAPY*

COMMANDER CALVERT STEIN (MC), U S N R †

THIS paper presents a report on the mass handling of large groups of borderline neuropsychiatric casualties on an open ward in the large naval hospital at Aiea Heights, Territory of Hawaii. The rapid turnover and the mixed diagnoses placed limitations on the program, but the group psychotherapy seems to have been much more important than medication in the rehabilitation of these men.

PROCEDURE

During the month of August, 1945, 285 patients, — seamen, specialists, petty officers and chief petty officers, — with diagnoses including the fatigue states, the various neuroses, some hysterias, somnambulism, mild epilepsy and various personality disorders, spent an average of ten to fourteen days en route from front-line hospitals to the United States. Almost all of them knew that they were headed for a prolonged stay in the United States, if not for an actual medical discharge. The effect of the cessation of hostilities during the middle of the month did not improve their status, nor did it diminish their complaints. On the contrary, there was observed a generalized increase of tension and restlessness, even on non-neuropsychiatric wards, and indeed even among the staff members, including corpsmen, nurses and medical officers. The average daily census on the ward was 115, and the average daily attendance at conferences was 85.

After sick call every morning, during which every patient was seen and given an opportunity to express a complaint, exchange a friendly greeting or make an appointment for a private conference later in the morning, — frequently by request, if he appeared to be unusually worried or ill, — the patients were invited to gather at one end of the ward for an informal talk. An average daily attendance of 74 per cent of these patients attested to the fact that the invitation was welcomed by most of them. They participated vigorously in discussions that covered a wide variety of topics, and often lasted not only well past the allotted hour but sometimes for several successive days. The subjects included health, diagnoses, — medical and surgical as well as neuropsychiatric, — the causes and treatment of the neuroses, insomnia, disturbing dreams, courtship, marriage, insurance, educational opportunities and problems and the Red Cross services.

*From the Neuropsychiatric Department of the United States Naval Hospital, Aiea Heights, Territory of Hawaii.

This article has been released for publication by the Division of Publications of the Bureau of Medicine and Surgery of the United States Navy. The opinions or assertions contained herein are the private ones of the writer and are not to be construed as official or reflecting the views of the Navy Department or the Naval Service at large.

†Neuropsychiatrist, Springfield Hospital, Springfield, Massachusetts (on leave of absence).

Nontechnical language, frequent interruptions for questions or comments, a blackboard and drawings, made by the patients themselves, and the presentation of actual case problems by the patients, usually anonymously, were the rule of the day. Occasionally a patient availed himself of the opportunity to leave the meeting whenever he chose to do so. A so-called "gripe box" was placed in the lobby, and its contents furnished the key to the particular day's discussions. Sample questions and comments are given below.

The average educational level of these men was the tenth grade. About two thirds of the group were married. Attendance on other duties, such as care of gear, special details, consultations and chapel attendance, cut down the average number of sessions attended to six, although many patients managed to be present at a dozen or more.

Some of the questions asked and comments made were as follows:

Could you explain the procedure that is followed when we return to the States? Do people think we are crazy, or what?

Does the pulse beat fewer times than the heart beats? If not, why doesn't it?

Please explain discrimination — not only of race but of color and creed — in the Service and in civilian life and between officers and enlisted men. Aren't some of us being a bit hasty in "judging other people's actions by our own"? To avoid any jumping at conclusions, the writer is white, of German-Dutch-English descent, a Mormon, and has spent quite a few years in both civilian life and in the Navy. Thank you for the help you have given all of us.

Suggest co-operative consideration among men in the Service. I believe this is a basic cause of a great deal of discontentment.

We have heard rumors that they send letters to our people stating that we are in the hospital, and we would like to know what they say if that is true.

What causes ulcers of the stomach, and can they be cured?

If a person in the family died with a cancer, is it possible for anyone else in the family to inherit one, and can they be cured?

How should one go about telling adopted children their status?

If you and your wife are nervous, will your child be nervous too — and what will be the cause?

Will you please explain the diagnosis of psychoneurosis, anxiety, and if we are given a medical discharge will "PN" be stamped on our discharge?

Will duty in the Pacific have any effect on making a person sterile?

What's the cause of talking, walking and screaming in one's sleep? What is the cure for this condition?

Good morning, Doctor. If a man has something on his mind concerning his wife and himself after they are married — something which she *should* know about — will you be so kind as to explain to the group a correct way to inform her about the trouble — the trouble being the couple can't have children — the male at fault, and in this certain case it is the female at fault.

These morning sessions are the bright spot of an otherwise drab routine.

half years as a prisoner of the Japanese. A few of his observations are given as a requisite to understanding the reaction of the neuropsychiatric patients to his story.

Out of about 3500 sick patients — all prisoners of war and most of them Americans — he recalled less than 50 who were neuropsychiatric casualties. The bulk of these were psychotic, and all were given the so-called "cage treatment," which was literal incarceration in an open cage, usually without clothing, with an inadequate supply of food, with no medication whatsoever and with frequently repeated abuse, violence, torment and torture — chiefly beatings, wettings and freezing. Even the vermin-infested mats were denied them for bedding, and they were often deprived of the half-rations usually accorded to other sick patients. When they died, the other patients were forced to stand by and watch their cremation, as a warning not to die — (sick prisoners cannot build airfields, and half-rations are no inducement to remain on the sick list). A temperature of 103°F or higher was required for admission to the sick list. A Japanese "doctor" performed alleged appendectomies without anesthetics (Red Cross supplies were unobtainable because they were needed to fill the black-market demand), and experimented with beriberi and other diseases by injecting intravenously aqueous solutions of whole soy bean preparations. The death of 8 of these unfortunate victims in succession did not deter his "research." The worst psychotic patient the soldier recalled was a homicidal maniac who was convinced that men were bent on killing him. He stood the cage treatment for six weeks, after which he returned to his duties, remaining cured from then on.

"Could you tell us," I asked the speaker, "whether you had many psychoneuroses, and approximately how many and what type?" He shook his head with a sad smile, and said, "They were too sick." Spontaneously his audience of 120 patients burst into honest and uncontrolled laughter.

Evidence of the protracted effects of the group talks can be seen from the following abbreviated reconstructive analyses.

CASE 1 A seaman, first class, with a ninth-grade education, who had been away from home for 2 months, for the first time, was admitted to the sick bay for nostalgia and an anxiety neurosis. After attending seven ward talks, he asked for help in regard to a lump in his throat that had suddenly appeared 3 nights previously.

The patient could think of nothing unusual that had occurred during the day of onset, but readily admitted that a lump in one's throat frequently denoted grief. He laughed at the suggestion that he might be thinking that someone was trying to choke him, and was equally certain that he had no organic disease in his throat.

On the day of onset, the patient had seen the moving picture "Wells Fargo." The scenes that he remembered were those in which the hero's mother-in-law salvaged the note written by her daughter and sent it to the Confederate enemy, causing the ambush and near death of her son-in-law. The patient had been keeping company with a young girl for

several years. He was sure that her mother would object to an early marriage, and was reluctant to admit that the reason he had not mentioned the existence of this girl to his mother was that he feared that she too would oppose the union. He realized that, unlike the hero in "Wells Fargo," a pioneer of the transcontinental delivery service, he was not returning as a hero, but that like him he was returning to a home of ever increasing value. He readily accepted the analogy that just as a problem in arithmetic might have several different answers, all of them correct, so there must be many factors contributing to his neurosis. Before the close of the half-hour interview he was able to apply this reasoning to two other functional complaints — pains in the region of the left breast and speeding up of the heart. His associations were as simple as they were obvious — "heart panic" or "heart ache." He did not know that heart failure was such a frequent cause of death, so that this phase of the interview was not pursued. He dwelt a little more on "heart throb," and left in a smiling and greatly relieved mood. Two weeks later his complaints had not returned, and his clinical status had greatly improved, notwithstanding the delay in his evacuation.

CASE 2 A 22-year-old, unmarried aviation mechanic, who was gaunt and underweight and appeared to be harassed, with a diagnosis of hysteria kept insisting that the pains in his perineum must be organic, and that even though the vertebral x-ray films and prostatic smears were negative, the only treatment that had given him any relief was the prostate massages he had received a few weeks previously. He had had 14 years of schooling.

During the initial examination he was asked whether the term "a pain in the ass" meant anything in particular to him. His response was a spontaneous grin, and he agreed to think over possible associations pending his next interview.

Several days later, and after repeated denials, the patient recalled his first experience of perineal distress. This and succeeding associations during four sessions of 20 minutes each, were as follows. At the age of 15 he visited a hospital where a favorite brother-in-law was recovering from serious mutilating injuries. On entering the hospital he experienced sharp distress in the perineum. The present complaint was similar but more accentuated. He had the same sensation whenever he visited a hospital if he saw anyone who was badly injured. He continued "About ten days ago at a picnic I was O.K. until it came time to come back [to the hospital]. Then it suddenly came back in the buns — I remember seeing a sign, 'Don't throw cigarette butts on the deck.' Yeah, I do sometimes call it my 'buntt.'" During his earlier period of hospitalization he had had to receive rectal tubes for relief of abdominal distention, the relief was pleasant, and eased his perineal distress. The use of the tube recalled his fear of hemorrhoids — from his straining at stool — and his buddies, who had had to have hemorrhoidectomies for painful and bleeding piles about a year previously, at the time of the onset of the present illness. His mother has used an enema daily, and she had not slept with his father for as long as he could remember. Once when drunk he thought that he had accomplished anal intercourse with his mistress, and had been ashamed of this ever since.

On the occasion of the last interview, at which these associations were uncovered, the patient entered smiling and demanded to be returned to duty on the ground that he had recovered. He was advised to take a few months at a convalescent hospital first. He stated that he began to "catch on" after the seventh group lecture — especially after the talk on constipation. On that day he stopped straining in order to test himself for the presence of the pain and suddenly discovered that it had left him. Except for two transient returns following sports, he has remained symptom-free for 3 weeks, for the first time in 11 months.

CASE 3 A 27-year-old, married carpenter's mate with an eighth-grade education had had 11 months of active duty, 7 of them overseas. The diagnosis was anxiety psychoneurosis. After his fifth session on the ward, he asked about a disturbing dream that had occurred on three successive nights a month earlier, causing him to awaken in a tense and anxious state. In the dream a strange man was entering his home in the United States and either kidnapping or killing his baby and assaulting his wife.

rupted the working day that they interfered with routine chores. There was also a noticeable decrease in requests for private interviews with the doctor, as well as a change in the nature of these interviews. Just as the bulk of the questions in the complaint box became predominantly psychosomatic and socio-marital in content, so the bulk of the private consultations became sharply confined to specific problems instead of covering the generalized psychosomatic complaints that formerly predominated. This increased insight is illustrated by the following remarks: "I think I know what caused my headaches, now, but why do they keep coming back on me?" — "That talk you gave on the changes in the stomach and guts when you're scared — well, I guess that's me alright, but what am I scared of now?" — "You mean to say I keep blaming myself for sumpin' I didn't have the nerve to finish way back then?" "But Doc, I tell you I *do* love my father, I — well, yes, there *was* one time when I was pretty mad at him for something he did." A review of some of the questions in the preceding section also gives a fairly accurate picture of the depth of interest and understanding that has been cultivated in these men.

Although there is obviously no way of measuring the effectiveness of abbreviated individual psychotherapy, it seems to have increased. This is shown objectively in the conduct of the men on the wards, their ability to sleep without sedation and their heightened interest in recreational and occupational therapeutic pursuits. This is in sharp contrast to my experience with similar cases on open neuropsychiatric wards where there has been no such group psychotherapy.

Invitations to outsiders to serve as group leaders or as guest speakers have also increased as a direct result of the interest shown by the patients. These guests have included chaplains, Red Cross workers, specialists in education and returning ex-prisoners of war. Some of the specific contributions are presented below.

There has been observed by corpsmen, nurses and the doctors a sharp decrease in the number and frequency of requests by patients for the most frequently used medications — sedatives, cathartics and aspirin. For technical reasons this cannot be proved statistically, but that it is true is attested by the fact that the observation was made spontaneously.

One of the difficulties in obtaining a statistically accurate report of this decrease was the fact that peace came during the first month of this program. One would expect it to have operated as a favorable therapeutic influence, but the fact is that for the first two weeks after the cessation of hostilities there was observed a general feeling of being let down, accompanied by mounting tension and anxiety over the delay of demobilization. This was noticed among the non-neuropsychiatric patients as well,

at times amounting even to actual friction and quarrels between patients and corpsmen. It was also easily discernible among the staff — the psychiatrists not excepted. Despite this, the demands for medication on this ward decreased*.

On one afternoon the irritability and restlessness of patients on two similar open neuropsychiatric wards reached unusual and in some cases almost hysterical proportions. The occasion was the announcement of an evacuation list on which some of the newly arrived patients had been placed, to the neglect of many of the earlier ones. The almost complete absence of such unrest on this ward was the result of a two-minute preliminary talk by the senior corpsman, a pharmacist's mate, second class. He explained that inequities and discrepancies often crept in, and that when a rush order came in for a quota to fill an unexpectedly available ship, some men whose records and disposition had been held up by requests for consultations or for laboratory studies, or on account of accumulations in the record office, might be delayed for a few days longer than others, but that in the long run the selections tended to balance up with reasonable fairness. So long as the patients knew that someone was taking an interest in them, that there was no intentional discrimination or neglect and that someone felt that they were important enough to deserve an explanation, they were reasonably satisfied. This conclusion is justified by the complete absence of complaints about the evacuation list in the complaint box on the following day. A few weeks later, with a new group of patients, when the preliminary talk had been unintentionally omitted, the box was again filled with protests over apparent inequities on the list.

The unsolicited reports of comments and discussions overheard among the patients that keep coming in from corpsmen, nurses and workers in other departments lend confirmation to the impression that the work is constructive. One observer said: "There was a complete absence of sensationalism, smirking or smut in their discussion of the question of whether the couple that had engaged in premarital intercourse should marry, and much of their discussion of intermarriage questions was on a distinctly highly intellectual plane."

PRISONERS OF WAR

In anticipation of the arrival of repatriated prisoners of war from Japan, it was the expectation of the psychiatrists at this hospital that not many psychotic or psychoneurotic patients would be encountered. This anticipation was fully realized.

One of the new arrivals, a pharmacist's mate, second class, was invited to meet with the group on the ward. In an informal way he presented a brief picture of some of his experiences during three and a

*On the closed neuropsychiatric wards there was observed during this same period a pronounced increase of depressed patients and of patients with deep anxieties over guilt as well as of suicidal attempts.

problems. Lecturers, teachers and clergymen of all denominations are learning that their most popular meetings are those in which they give to their respective fields a liberal and human interpretation. Many of these leaders have been conducting group psychotherapy for centuries. Much more of this sort of "treatment" is needed.

MEDICAL PROGRESS

OPHTHALMOLOGY

EDWIN B. DUNPHY, M.D.*

BOSTON

IN the past year there have been no outstanding advances in ophthalmology. Two subjects, however, have been selected on the basis of general interest.

PENICILLIN IN OCULAR INFECTIONS

Enough time has elapsed since the introduction of penicillin to evaluate its efficiency in treating diseases of the eye. The literature abounds with case reports of alleged cures, but in many of these the penicillin has been used along with sulfonamides and other drugs, so that its true therapeutic role is difficult to determine. One fact, however, stands out clearly: penicillin is usually superior to the sulfonamides for several reasons. It is generally nontoxic, whatever route of administration is chosen¹, its antibacterial action is not inhibited by autolytic products and secretions², it has little if any deleterious effects on the regeneration of corneal epithelium³, and it is not incompatible with other frequently used drugs, such as atropine, cocaine, procaine and sulfadiazine.^{4,5} With these advantages it should be the drug of choice in treating any ocular infection known to be due to penicillin-sensitive organisms. Unless, however, certain basic facts are understood regarding its distribution in the ocular tissues by various methods of administration, many cases will not be treated effectively, and much valuable time will be lost before the ocular infection can be brought under control.

In 1944, Struble and Bellores,⁶ using rabbits and dogs, showed that when penicillin was injected intravenously in large amounts it was concentrated in the ocular tissues as follows, in descending order: the extraocular muscles, the conjunctiva, the sclera, the choriorretinal tissue and aqueous. Only a trace was found in the cornea and vitreous, and none was found in the lens. When, however, penicillin was applied locally by corneal bath, a much higher concentration was found in the conjunctiva, sclera,

iris and aqueous than when it was given either intravenously or subconjunctivally.⁷

The same year, von Sallmann and Meyer⁸ showed that repeated instillations of penicillin solution or ointment in the eyes of rabbits produced no detectable antibacterial activity on the part of the aqueous, even with the addition of wetting agents, which usually enhance the passage of various substances through the cornea. A corneal bath, however, resulted in high levels in the aqueous. These investigators also found that by iontophoresis the penicillin passed easily into the aqueous, the latter exhibiting an antibacterial activity for four hours after a single application. The amount recoverable in the aqueous by this method was calculated as being ten times greater than that by the corneal-bath technic.

Leopold and LaMotte⁹ also showed that local instillations were ineffective in getting penicillin into the aqueous of normal rabbits' eyes, on the other hand, this simple method worked quite well when the corneas were abraded or if experimental corneal ulcers had been produced beforehand. The concentrations in the aqueous in these inflamed eyes were well above the required therapeutic level, as defined by Rammelkamp and Keefer,¹⁰ who state that the concentration in serum required for maximum bacteriostatic effect is 0.019 units per cubic centimeter for *Streptococcus haemolyticus* and 0.15 units for staphylococcus. These authors therefore concluded that the elaborate iontophoretic technic was probably unnecessary in dealing with infected corneas when simple instillations appeared to be adequate.

Apparently, intramuscular injections also fail to produce any appreciable concentration of penicillin in the aqueous of normal rabbits, but they may do so when corneal ulcers have been produced beforehand.^{2,8,10}

The application under the lid of a small cotton pack saturated with a solution of penicillin containing 20,000 units per cubic centimeter has been

*Clinical professor of ophthalmology, Harvard Medical School, and chief of ophthalmology, Massachusetts Eye and Ear Infirmary.

For over 10 minutes the patient insisted that he could think of no association, but he finally reluctantly stated that his brother had been unfaithful to his wife and had been caught and forgiven. The patient greatly admired his sister-in-law and felt her wrongs deeply. On the next interview he reported an affair of his own with a former sweetheart and his fear lest his wife should discover it and leave him. One week later he came in to report considerable anxiety over a photograph of himself that he had impulsively sent to the girl friend with an affectionate caption. The picture was sent in June. He regretted sending it at once and requested its return a few days later. An answer was expected in July, but none had yet arrived. The patient reported at the sick bay with his anxiety psychoneurosis on July 15.

It was suggested that even if the unlikely did happen and his wife heard about the episode or saw the picture, there were after all many other things that he had done in June that he did not remember. Apparently the idea of pleading amnesia, together with error, appealed to him, although he rejected it strongly, for 3 days later he reported "I've been sleeping sound the last few days with all the racket—the boys tell me we had a rumpus during the night but I never even heard it." From his account it seemed probable that the picture had been destroyed or would be returned when his mail caught up with him. Insight into the causes of his dream and his bipolar affection for his sister-in-law, together with his exaggerated fear of losing his wife, seems to have been the chief cause of his improvement, which persisted clinically for the rest of his stay of 3½ weeks.

There have been dozens of cases with similar problems, affecting chiefly sleep and functioning of the gastrointestinal tract, that have shown striking improvement, if not recovery, over extremely brief periods of time. Since this improvement occurs in men with a history of continued complaints for months and sometimes years, it is believed that, contrary to popular opinion, it is not necessary to undergo prolonged psychoanalysis or to have a superior education to profit from concentrated psychotherapy.

DISCUSSION

In view of the natural limitations of analytical, hypnotic and narcotherapeutic procedures, and because of the large turnover of borderline neuropsychiatric casualties in this hospital, an attempt has been made to apply the well known principles of group therapy on a somewhat larger scale than has usually been reported.^{1,2}

As was pointed out in a previous paper, there is ample Biblical precedent for the principles of mental hygiene in group therapy.³ The following excerpts from the "Book of Proverbs" bear repetition.

A wise man is strong—by wise counsel thou shalt make thy war, and in multitude of counselors there is safety (24 5-6)

Debate thy cause with thy neighbor himself (25 9)

A scorner seeketh wisdom, and findeth it not (14 6)

He that answereth a matter before he heareth it, it is folly and shame unto him (18 13)

A merry heart doeth good like a medicine [and] maketh a cheerful countenance (17 22, 15 13)

A man that hath friends must show himself friendly, and there is a friend that sticketh closer than a brother (18 24)

Chasten thy son while there is hope, and let not thy soul spare for his crying (19 18)

Labor not to be rich (23 4)

A good name is rather to be chosen than silver or gold (23 1)

Withhold not correction from the child, for if thou beatest him with a rod, he shall not die (23 13)

A man's gift maketh room for him, and bringeth him before great men (18 16)

A brother offended is harder to be won than a strong city, and their contentions are like the bars of a castle (18 19)

It is better to dwell in the wilderness than with a contentious and an angry woman (21 19)

These and similar proverbs, one of which was posted each day on the bulletin board, gave both strength and dignity to our discussions of the commonly accepted teachings of mental hygiene. The majority of the men appear to have learned in an average of half a dozen sessions that a diagnosis of psychoneurosis is not a permanent stigma, that it is a valuable safety valve, and that as such it is a promising and constructive key to a better understanding of their personalities. They readily grasped the idea that any organ may act as a safety valve, and that when the valve was released through a functional disorder—that is, when a neurosis appeared,—three facts were immediately known both to the patient and to the doctor: first, that the inside (emotional) pressure was too great, second, that the valve was functioning normally, and third, that the boiler—the body and brain—was being saved from immediate damage.

A gratifyingly large number of men have reported, without solicitation, that they have noticed a pronounced improvement in health even without follow-up interviews, and often even before they learned of their disposition (evacuation to the United States). Ten patients during the month of August made a sincere request to be returned to duty on the ground that they had fully recovered.

It may be re-emphasized that a great deal of the success of the program is in large measure dependent on the initial interview, in which each patient is given a brief but adequate neurologic and psychiatric examination and an appraisal is made independently of the data contained in his health record.⁴

CONCLUSIONS

The dignity of human companionship and free discussion as a daily accompaniment of the rehabilitation program is a proved and valuable adjunct to physical, medical, occupational and recreational therapy. The nature of the questions and discussions is excellent proof of the earnest desire of most psychoneurotic patients to understand their problems and to do something constructive about them. Limitations of intelligence and education do not seem to be a barrier to the execution of such a program. Much depends on the group leader, but almost any person, whatever his profession, may start such a program if he understands the dynamics of human behavior and maintains a sympathetic attitude toward psychosomatic problems. For such subjects as he may not feel qualified to discuss there will always be experts who will be willing to contribute what they can. For patients of any class it is important that they shall feel that their emotional and personal problems are just as much in need of study and guidance as are their physical and organic

Rycroft²¹ also reported some experimental work with subconjunctival injections of penicillin in human eyes. Ten eyes hopelessly blind and scheduled for removal were given subconjunctival injections of 0.25 cc of a solution of penicillin containing 4000 units per cubic centimeter. After intervals of fifteen, thirty and sixty minutes, aspiration of 0.12 cc of either aqueous or vitreous was performed. It was found that penicillin reached the aqueous after fifteen minutes in 7 of 8 cases. Three of 6 cases showed penicillin in the vitreous after forty-five minutes.

Quantitative determinations on human eyes were made by von Sallmann.¹¹ He selected four eyes about to be enucleated for various conditions—two for malignant melanomas near the disk, one for absolute glaucoma and one for an old injury from an intraocular foreign body. In three eyes he inserted under the lid cotton packs soaked with a solution of penicillin containing 20,000 units per cubic centimeter for one hour. Aqueous determinations showed 2.3 units of penicillin in one case of melanoma and zero units in the other. In the case of absolute glaucoma 9 units per cubic centimeter was found. In the remaining eye, that with the old injury, 4 drops of a solution of penicillin containing 20,000 units per cubic centimeter were instilled and the eye was enucleated two hours later. The aqueous contained 0.5 units per cubic centimeter. Hence, observations on human eyes have been erratic, but generally speaking the average amount of penicillin found in the aqueous is much less than that found in rabbits' eyes.

The weight of experimental evidence indicates the following recommendations for treating eyes infected with penicillin-sensitive organisms. First, intramuscular and intravenous injections of penicillin probably have little effect in controlling infections of the anterior and vitreous chambers. Second, subconjunctival injections may have some effect on infections of the anterior chamber but are probably worthless in infections of the vitreous. Third, infections of the vitreous can probably be most effectively treated by a single intravitreal injection of 0.1 cc of penicillin solution containing not more than 500 units. Fourth, infections of the anterior chamber are likely to be controlled by local application of saturated cotton packs or by iontophoresis. Corneal bath and subconjunctival injection will probably be less effective. In cases of perforating corneal injury with damage to the lens, a single injection of 0.1 cc of a solution of penicillin containing not more than 500 units may be justified. Lastly, for conjunctivitis and infected corneal ulcers, frequent instillations of penicillin drops or ointment will probably be effective. Saturated cotton packs under the lids, iontophoresis or corneal bath should be tried in extremely severe cases.

So much for the experimental work. Case reports of the clinical use of penicillin fill the literature. The

most striking ones deal with cures of gonorrheal conjunctivitis.²²⁻²⁵ Apparently this disease may be effectively treated either by frequent local instillations or by intramuscular injections alone, since the original work of Struble and Bellows⁶ showed that systemic treatment resulted in high concentrations in the conjunctiva. When the cornea is involved, however, it seems wise to use local applications in addition to intramuscular or intravenous injections.

Although no definite dosage or frequency of application has been determined for surface infections, the tendency has been toward higher concentrations and more frequent applications. Thus, Sorsby and Hoffa²⁶ report 47 cases of ophthalmia neonatorum, most of them due to the gonococcus, in which the best results were obtained by using penicillin drops (2500 units per cubic centimeter) every thirty minutes for the first three hours, every hour for the next twenty-four hours, and every two hours for the next two days. Under this regime 21 of 22 cases received a complete clinical cure within one hundred hours. In other groups of cases treated with lower concentrations and less frequent applications, no such high percentage of cures was obtained.

Marginal blepharitis appears to be a condition in which penicillin can be of great value. The usual procedure is to rub penicillin ointment containing 1000 units per gram into the lid margins three times daily. Florey, McFarlan and Mann²⁷ report 48 cases treated in this manner. Cure was complete in three to ten weeks, no other treatment being used. A follow-up of these patients after a year without treatment showed that 66 per cent remained free from recurrences.

Orbital cellulitis has been successfully treated by Sloane²⁸ with the use of intramuscular injections.

The reports of the treatment of corneal ulcers are encouraging. Juler and Young²⁹ and Cashell³⁰ report series in which a rapid cure was obtained in the great majority of cases by frequent instillation of penicillin drops containing 500 units per cubic centimeter.

There have been several favorable reports³¹⁻³⁵ on the direct injection of penicillin into the anterior chamber for infections following perforating injuries. In some cases dramatic improvement has taken place after all other methods aimed at the control of the infection have failed. A single injection of 100 units has usually been sufficient.

No reports on intravitreal injections in the human eye have appeared in the literature, but on the basis of experimental work it seems justifiable to employ them in certain cases of vitreous abscess after perforating injuries. One should be careful to limit the injection to 0.1 cc containing 250 units and to place the injected fluid as near as possible to the center of the vitreous, so that little if any contact is made with the retina.

shown by von Sallmann¹¹ to be extremely effective in producing high concentrations in the aqueous, cornea and iris

The intravitreal penetration of penicillin has been the subject of much experimental work. According to Leopold,¹³ intramuscular and intravenous injections of as much as 4000 units per kilogram of body weight have failed to produce detectable concentrations in the vitreous of normal rabbits. The results following subconjunctival injections have not been uniform, one investigator¹² finding fair levels of penicillin in the vitreous of normal rabbits' eyes and others⁶ finding extremely inadequate levels.

The results of these various investigations on normal eyes can now be correlated with some of the experiments designed to test the efficacy of penicillin in combating experimental infection.

Robson and Scott¹³ successfully treated experimentally produced staphylococcal ulcers on the corneas of rabbits by frequent instillations of a penicillin solution consisting of 500 units per cubic centimeter.

Using rabbits, von Sallmann,¹⁴ by introducing 0.05 cc of a diluted broth culture of pneumococcus (Type 3, 7 or 10) into the anterior chamber, produced a standard infection with simultaneous injury to the lens. Treatment by penicillin iontophoresis was begun six and twelve hours later and was continued for two or three days. The infection was checked in all cases, even after twelve hours, whereas the eyes of the control animals went on to destruction.

Von Sallmann¹⁵ repeated the same experiments using various strains of penicillin-sensitive staphylococci. Penicillin applied by iontophoresis six hours after inoculation controlled the infection in 62 per cent of the eyes so treated. An intralenticular injection of *Clostridium welchii* caused a destructive endophthalmitis, which was not influenced by penicillin therapy.

Direct injection of 0.1 cc of penicillin solution—2500 units per cubic centimeter—into the anterior chamber of the normal rabbit's eye has been shown by Dunnington and von Sallmann¹⁶ to be relatively harmless, but more than this may cause serious damage. This method has been made use of by Scobee,¹⁷ who produced perforating corneal injury in a number of rabbits and then infected the anterior chambers with hemolytic *Staphylococcus aureus*. A solution of penicillin containing 500 units per cubic centimeter was then introduced into the anterior chambers on successive days, but this succeeded in controlling only the mild infections, the severer ones not being affected.

Town, Frisbee and Wisda¹⁸ were able to cure experimental streptococcal infection of the anterior chamber of rabbits' eyes by massive doses of penicillin given intramuscularly, provided no injury to the lens had taken place. They point out that in infections of the anterior chamber a direct injection

of penicillin following a withdrawal of aqueous may be dangerous owing to extension of the infection at the site of the needle puncture.

Von Sallmann and his associates^{19, 20} have shown that the normal rabbit's eye tolerates a direct intravitreal injection of 500 units of penicillin. More than one injection or the giving of more than 500 units in a single one may cause serious damage. Since others¹⁰⁻¹² have shown that intravenous injections, subconjunctival injections, iontophoresis and application of saturated cotton packs all fail to produce more than traces of penicillin in the vitreous, von Sallmann²⁰ tried intravitreal injections in experimentally produced vitreous infections of rabbits' eyes. Each of ten eyes received 0.05 cc of a diluted broth culture of a Type 3 pneumococcus introduced directly into the center of the vitreous. Treatment was begun eight hours later by an intravitreal injection of 0.1 cc of penicillin containing 100 units. All ten eyes recovered completely. The same intravitreal injection was found equally efficacious in staphylococcal infections of the vitreous, in which even 10 units of penicillin checked the infection in all ten eyes. The therapeutic effect was, however, greatly enhanced when a dose of 400 units was injected. Leopold¹² also found that experimental staphylococcal infections of the vitreous of rabbits could be halted by an intravitreal injection of 500 units of penicillin.

Subconjunctival injections of penicillin have been found totally ineffective against experimental pneumococcal infection of the vitreous in rabbits by von Sallmann²⁰ and only partially effective against staphylococcal infection by Leopold.¹² Likewise, intravenously administered penicillin has failed to halt experimental vitreous infection in rabbits.

It must be borne in mind that conclusions reached from experiments on animals' eyes do not necessarily apply to human eyes. It is therefore necessary to examine carefully some of the few human experiments available. One of the first of these was made by Rycroft,⁴ a medical officer in the British Eighth Army in Africa. Shortly after death he removed five normal eyes from 5 soldiers who had been receiving large amounts of penicillin intramuscularly. Penicillin assays were carried out on the aqueous and vitreous, but no inhibition of bacterial growth could be detected. These determinations, however, were made six hours after death and fourteen hours after the last administration of penicillin, so that one might not expect any results. Rycroft then removed seven badly damaged eyes from soldiers receiving large doses of penicillin intramuscularly. In these cases the last dose of penicillin had been given within three hours, but even here no detectable amounts could be found in the aqueous or vitreous. It thus appears that although intramuscular injection may be effective in the case of damaged rabbits' eyes, it is not necessarily so in damaged human eyes.

sive changes. Normally it disappears toward the end of fetal life, but occasionally it persists and forms firm connective tissue in back of the lens.⁶⁴ In the 50 cases reported, 30 infants were premature and 20 were full term. Of the premature infants, 28 showed bilateral involvement and 2 unilateral involvement. Of the full-term infants, the involvement was bilateral in 7 and unilateral in 13. Thus, 35 of the 50 cases were bilateral and 15 were unilateral.

Reese and Payne believe that the same factor that precipitates early birth may also cause the eye lesions. Although no convincing evidence is presented, the authors think that maternal infection may be a factor. A history of uterine bleeding was obtained in 12 of the mothers in their series. Maternal infection is known to cause congenital anomalies in the offspring, as has been shown in the connection between rubella during pregnancy and congenital cataracts.⁶⁵

So far as treatment is concerned, many suggestions have been made. If one accepts the theory of the deleterious effect of light, these premature infants should be kept in a dark room for some weeks as a prophylactic measure. Mydriatics may be used not only to put the iris at rest but also to break up posterior synechiae, which often occur.⁶⁶ Miotics may have to be used in the cases in which glaucoma develops.

Attempts to seal off the hyaloid artery with diathermy have been unsuccessful.⁶⁰ Operations designed to establish new vascular connection between the episcleral vessels outside the eye with the ciliary body are of doubtful value.⁶³ Surgical attempts to remove the lens substance and make a vertical cut in the retrolental tissue have resulted in varying degrees of success.⁶⁴ Irradiation has been suggested as a likely means of closing the blood vessels in the fibroblastic tissue.⁶⁶ In a few cases partial retrogression of the opaque connective tissue behind the lens has been observed without any treatment, but the eyes have never developed normally.

The results of penicillin therapy in nonspecific uveitis have been disappointing, although occasionally favorable results have been reported. The most complete report on this subject is that of Irvine and his associates,³⁶ who treated 56 cases of all types of uveitis with intramuscular injections of penicillin and 8 additional cases by penicillin iontophoresis. Only in 9 cases of iridocyclitis was any significant improvement noted, and this was said to be no greater than would have been expected from the usual forms of therapy.

Syphilitic uveitis may be expected to respond to penicillin, and such has been found to be the case in the report of Klauder and Dublin³⁷ of 3 cases treated with large doses intramuscularly.

According to Darius,³⁸ trachoma has responded favorably to penicillin instillations, but the improvement observed was said to be in no way better or more rapid than that seen with sulfonamides.

The treatment of dacryocystitis has not been satisfactory. Bellows³ states that the discharge becomes sterile but no clinical recovery takes place.

In cases in which doubt exists concerning the nature of the infecting organism, there is no reason why the sulfonamides may not be employed along with penicillin. Although it has been shown that no incompatibility exists between the two drugs, either *in vitro*⁴ or *in vivo*,³⁹ experimental work indicates that the effect of one does not enhance that of the other.³⁹

Sensitivity of the ocular tissues to penicillin has been occasionally reported.^{5, 40-43} This usually occurs in the form of redness and swelling of the lids, although some cases of generalized urticaria have been seen.

RETROLENTAL FIBROPLASIA

Persistence of the embryonic blood supply of the lens, the tunica vasculosa lentis, is occasionally seen in full-term infants.⁴⁴⁻⁴⁸ It is usually unilateral and has been regarded as a purely local disturbance. What appears to be another phase of this disease is a progressive growth of opaque embryonic tissue behind the lens, which occurs, usually bilaterally, in a number of premature infants after birth. The nature and prevalence of this condition are just beginning to be understood, largely through the work of Terry,⁴⁹⁻⁵⁵ who has given it the name of "retrolental fibroplasia."

The syndrome consists of widespread ocular changes related to persistence of the hyaloid artery and tunica vasculosa lentis, to growth of embryonic connective tissue behind the lens and to persistence of the fetal fibrillar vitreous. The typical changes are shallow anterior chambers, microphthalmia, a fetal-blue color of the iris, searching nystagmus and often retinal separation. Glaucoma and cataract may also occur, and spontaneous hemorrhage into the anterior chamber of vitreous has been reported.⁵⁶ The condition has sometimes been mistaken for retinoblastoma.⁵⁷⁻⁶¹

The incidence of this condition is apparently increasing, probably owing to the greater survival rate of premature infants during the last decade. Clifford⁶² of the Boston Lying-in Hospital found that 12 per cent of infants weighing 3 pounds or less at birth developed this disease. Terry,⁵⁵ using this figure along with statistics compiled by the Children's Bureau of the United States Department of Labor on the annual survival rate of 3600 extremely premature infants, has estimated that a minimum of 432 will be blinded by this cause yearly.

How this condition is brought about is the subject of much speculation. Normally the tunica vasculosa lentis consists of a network of blood vessels surrounding the lens.⁶³ The parent vessel of this system is the hyaloid artery. Venous drainage takes place through the pupillary portion of the tunica, the so-called "pupillary membrane," to the anterior surface of the iris. This whole system is designed to nourish the lens at a stage when the aqueous humor has not yet formed. After the ciliary body begins to produce aqueous, the lens has a new source of nutrition and the need for this elaborate vascular system ceases. Normally at eight and a half months the hyaloid system ceases to carry blood.⁶³

Although there is no direct proof of any one of the many possible causes for persistence and overgrowth of the embryonic vascular system, the most tenable theory, according to Terry,⁵⁵ is the effect of precocious exposure to light in these premature infants. This activates the musculature of the iris before the disappearance of the hyaloid vascular system. The resulting disturbance of the blood supply of this region may prevent aqueous from being formed. This in turn leaves the crystalline lens dependent on the hyaloid artery and tunica vasculosa lentis, and thus this embryonic vascular system persists, instead of regressing.

Terry has stressed the fact that retrolental fibroplasia is more than a persistence of the tunica vasculosa lentis, which consists only of blood vessels and contains no connective tissue. The condition under discussion has as its prominent feature an actual overgrowth of embryonic connective tissue, which, Terry believes, takes place to furnish support for an abnormally developed vascular system. Some of his reported cases have not shown this abnormal hyperplasia until some weeks or months after birth.

Unsuccessful attempts have been made to reproduce the disease in animals whose eyes at birth are extremely underdeveloped, such as the rat and the opossum.

A slightly different viewpoint regarding the development of this condition is held by Reese and Payne,⁵⁶ who have recently reported 50 cases. They believe that the retrolental fibroplasia occurs before birth and is chiefly due to persistence of the primary vitreous, which is vascularized mesoderm. This mesoderm may undergo either progressive or regres-

views of the Massachusetts Medical Society regarding how to afford our own veterans the best of medical care outside of veterans' hospitals

We believe that when such a contract is under consideration there should be at hand one or more duly appointed representatives of the Massachusetts Medical Society empowered to approve any minor changes in the fee schedule that might prove advantageous

As part of his committee's report Dr McCarthy submitted a schedule of fees for medical services rendered under the Veterans Administration Medical Care Program. This schedule, as amended by the Council, is given in Appendix No 2. In moving the acceptance of the report, he said that each member of the Council had received it well in advance of the meeting. The motion to accept the report was seconded by Dr Peirce H Leavitt, Plymouth, and it was so ordered by vote of the Council.

Dr Albert A Hornor, Suffolk, moved that the Council go into executive session. This motion was seconded by Dr Elmer S Bagnall, Essex North, and it was so ordered by vote of the Council.

At this point in the meeting the Council went into executive session.

At 5 30 p m Dr Daniel B Reardon, Norfolk South, moved that the Council rise out of executive session. This motion was seconded by Dr Leavitt, and it was so ordered by vote of the Council.

The President announced that the Council had risen out of executive session.

It was moved by Dr Leavitt and seconded by Dr Charles C Lund, Suffolk, that the Council adopt the part of the committee's report dealing with the fee schedule as amended by the Council, with the understanding that any contract that concerns this fee schedule would be reviewed by the Massachusetts Medical Society within a year.

In the debate attending this motion, it was explained by Dr McCarthy that the duration of any contract that the Blue Shield as administrator entered into with the Veterans Administration would be for one year and that, at the end of six months, either of the signatories might make suggestions regarding its revision.

The motion was adopted by vote of the Council.

It was moved by Dr McCarthy and seconded by Dr Reardon, that the Council approve of the plans whereby the hospital expenses of veterans who are being cared for in civilian hospitals be met by the Blue Cross, acting as administrative agent of the Veterans Administration, and whereby the costs of professional services of civilian physicians, who are caring for veterans under the fee schedule adopted be met by the Blue Shield, acting as administrative agent of the Veterans Administration.

In the debate attending this subject, the Kansas Plan was discussed. Under this plan a schedule of fees has been set up and agreed on by the Kansas Medical Society and the Veterans Administration. The medical society furnishes the Veterans Adminis-

tration with a list of physicians willing to serve under the schedule. The Veterans Administration acts as its own administrative agency. The medical society confers with the Veterans Administration from time to time as problems that concern both arise. It was emphasized that no actual contractual arrangements had been entered into and that this plan was on the basis of a gentlemen's agreement. It was pointed out that in Kansas there was no organization comparable to the Massachusetts Medical Service (Blue Shield).

In reply to a question, Dr McCarthy said that the contract that the physician participating in Blue Shield enters into concerns the administration of surgical and obstetric services only. He explained that this was not an all-inclusive contract and that the contract signed by the Blue Shield and the Veterans Administration would be all inclusive from the standpoint of the services offered. He added that the fee schedule now in force under the Blue Shield had nothing to do with the plan proposed.

In reply to a question, Dr Norman A Welch, Norfolk, said that the Blue Shield is open to any licensed practitioner of medicine in Massachusetts.

The motion was adopted by vote of the Council.

Dr Reardon moved that the final approval of any contract entered into with the Veterans Administration concerning the Massachusetts Medical Society be delegated to the Executive Committee of the Council. This motion was seconded.

It was explained by the Secretary that the Executive Committee was in approval of this motion, whose intent was to make it unnecessary to call the Council together for the sole purpose of formally approving a contract that would be based on the agreements reached at this meeting of the Council.

The motion was adopted by vote of the Council.

Dr Leavitt moved that when the contract heretofore referred to was under consideration in Washington, there should be on hand one or more duly appointed representatives of the Society empowered to approve any minor changes in the fee schedule that might prove advantageous. This motion was seconded by Dr Alexander J A Campbell, Suffolk.

Dr Albert A. Hornor, Suffolk, moved as an amendment to the motion the deletion of the words "in Washington." This amendment was seconded by Dr Dwight O'Hara, Middlesex South. The motion as amended was adopted by vote of the Council.

The Secretary, speaking for the Executive Committee, made the following recommendation:

Certain questions arose in the committee that had to do with circumstances that concern the payment of the physician giving the prenatal and postnatal care, but not delivering the case. This same type of discussion arose in connection with the preoperative and postoperative service rendered by the physician who did not perform the operation involved. This discussion also concerned itself with the fees that should be allowed the surgeon's assistant at operations.

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Special Meeting, April 10, 1946

THE Council of the Massachusetts Medical Society met in special session on Wednesday, April 10, 1946, in Building E, Harvard Medical School, Longwood Avenue, Boston. The meeting was called to order by the president, Dr Reginald Fitz, at 10 30 a m. Dr Michael A. Tighe served as secretary. One hundred and forty-four councilors were present (Appendix 1).

In opening the meeting Dr Fitz stated that the Council had not met in Harvard Medical School since 1825. He added that before that date it had met in this school several times. He said that this gave a certain historic interest to the meeting.

He introduced Dr C. Sidney Burwell, dean of Harvard Medical School, who spoke of the close relation that existed between the Massachusetts Medical Society and Harvard Medical School in the infancy of both and who added that, in their maturity, they were still not very far apart. Dr Burwell graciously welcomed the councilors and asked them to come again.

The business before this meeting was the report of a special committee, which had been appointed to confer with Major General Hawley, medical director of the Veterans Administration, concerning the medical care of veterans by civilian physicians.

The report of this committee presented by Dr Humphrey L. McCarthy, Norfolk, chairman, as amended by the Council, is as follows:

On February 6, 1946, the appointment of the Special Committee on Veterans' Care, comprising J. J. Dunphy, Worcester, H. L. McCarthy, Norfolk, and M. A. Tighe, Middlesex North, was formally confirmed by vote of the Council. This committee had been appointed in January by the President as a matter of emergency and at the request of Major General P. R. Hawley, of the Veterans Administration in Washington, who asked for a committee from the Society to confer with him about the medical care of veterans in Massachusetts.

Throughout its work, this committee has steadfastly borne in mind the Council's belief that the most satisfactory and economical care of veterans in Massachusetts could be obtained by granting them free choice of physicians in their own communities, this service to be paid for at prevailing rates, and, if hospitalization were required, by granting them hospitalization privileges in local licensed hospitals of their own choice.

Here is reported the committee's actions:

On January 14, 1946, the committee went to Washington to meet with General Hawley's representative. We were informed that the Veterans Administration favored

the local care of veterans along the lines approved by the Council. Up to that time, two types of contract to meet this general aim had been established, one with the Michigan Medical Service and another with the Kansas Medical Society.

Under the Michigan plan, doctors affiliated with the Michigan Medical Service who wished to take care of veterans were to be paid according to an agreed fee schedule through the Michigan Medical Service, which in turn was to be paid by the Veterans Administration. The Michigan Medical Service was to collect the amount to be paid for professional care plus 7 per cent, the latter sum representing the estimated costs necessary to the administration of such a plan.

The Kansas plan entailed the Society's submitting a list of its members who desired to work for the Veterans Administration under an established fee schedule. The society was to zone the state in an appropriate manner, offices of the Veterans Administration were to be established where needed and were to administer the plan directly.

Under either plan, a fee schedule was required. Therefore, the committee was informed that a fee schedule acceptable to participating doctors in Massachusetts was the first step in the development of any plan for veterans' care in this region outside that offered in veterans' hospitals.

We have constructed a fee schedule, which has been built up as fairly as possible, and in our judgment represents an honest appraisal of charges prevailing among Massachusetts practitioners for the services listed. The figures were obtained by consultation with individual physicians, with groups of physicians in different parts of the Commonwealth, and from representatives of the various specialty boards and special societies who happen to be residents of the Commonwealth.

We recommend the adoption by the Massachusetts Medical Society of this fee schedule as the first step in the activation of a plan for offering Massachusetts veterans optimum medical care by civilian physicians and in civilian hospitals.

We were given to understand that contractual arrangements might be established between the Veterans Administration and the Blue Cross-Blue Shield, whereby the hospital expenses of veterans in civilian hospitals would be met by the Blue Cross as agent and whereby the costs of professional services of civilian physicians caring for veterans under the fee schedule would be met by the Blue Shield as agent.

We believe that this plan is preferable to the Kansas plan and recommend its adoption. We have consulted with both the Blue Cross and the Blue Shield and have been informed that they are willing to undertake its administration. The Blue Shield agrees that an 8 per cent charge for expenses of administration is reasonable.

Should the Council adopt the plan thus outlined, we believe that the next step is for our attorneys and the attorneys of the Blue Cross and the Blue Shield to frame a contract acceptable to the three organizations involved. We recommend that final approval of any such contract as it concerns the Massachusetts Medical Society should be delegated to the Executive Committee.

Such a contract in its final form should then be presented to the proper authorities. It would represent the

*The charges for inoculations referred to in these schedules do not include the cost of material used

It was thought that \$54.00 should be allowed for the physician giving the prenatal and postnatal care, and that in simple cases \$54.00 should be allowed for the physician delivering the case. In difficult cases, a consultant delivering the case should receive a fee of \$75.00. In this discussion it came out that this division of fees represents an administrative detail that should not appear in the schedule but should go, as a recommendation, to the administrative agent, which, in this case, it is hoped will be the Blue Shield.

The Secretary moved the adoption of this recommendation. This motion was seconded and it was so ordered by vote of the Council.

The Secretary continued:

The Executive Committee being conscious that such administrative problems may be numerous, at least during the early days of the administration of this plan by the Blue Shield, offers the following recommendation:

That a special committee of five be appointed by the President, and that this committee, representing the Massachusetts Medical Society, be empowered to act in an advisory capacity to the Blue Shield in the interpretation of the Veterans' Fee Schedule.

The Secretary moved the adoption of this recommendation. This motion was seconded by Dr. Leavitt, and it was so ordered by vote of the Council.

Dr. Leavitt moved the adoption of the report as a whole and as amended. This motion was seconded by Dr. Reardon, and it was so ordered by vote of the Council.

At the suggestion of the President, the Council extended a rising vote of thanks to the members of the committee who so devotedly put this report together.

It was moved and seconded that the Council adjourn. This motion was adopted by vote of the Council.

The President declared the Council adjourned at 6:30 p.m.

MICHAEL A. TIGHE, *Secretary*

APPENDIX NO. 2

FEE SCHEDULE APPROVED BY THE COUNCIL OF THE MASSACHUSETTS MEDICAL SOCIETY FOR MEDICAL SERVICES RENDERED UNDER THE VETERANS ADMINISTRATION MEDICAL CARE PROGRAM

Dermatology (including syphilis, granuloma inguinale and lymphopathia venereum)

1. Office	
a. Consultation	\$16.20
b. Visit	
(1) Initial (history, examination and prescribing)	10.80
(2) Subsequent prescribing	5.40
c. Dressings	5.40
d. Unna boot	10.80

for anesthesia supervision of premedication, selection of anesthetic agents and methods, the administration of anesthetic agents, the treatment of all complications pertaining to anesthesia during the operation and postoperatively and the treatment of certain medical conditions, such as pulmonary and other conditions requiring the services of an anesthesiologist — i.e. asphyxia, drug poisoning, caisson disease, asthma, convulsions, etc.)

a Inhalation anesthesia

- (1) Ether — up to $\frac{1}{2}$ hour 10 80
Each additional $\frac{1}{2}$ hour 5 40

(2) Gas

(a) Conventional

- (1) Nitrous oxide up to $\frac{1}{2}$ hour 10 80
Each additional $\frac{1}{2}$ hour 5 40
(2) Ethylene, up to $\frac{1}{2}$ hour 10 80
Each additional $\frac{1}{2}$ hour 5 40
(3) Carbon dioxide, up to $\frac{1}{2}$ hour 10 80
Each additional $\frac{1}{2}$ hour 5 40
(4) Oxygen, up to $\frac{1}{2}$ hour 10 80
Each additional $\frac{1}{2}$ hour 5 40

(b) Special

- (1) Cyclopropane, up to $\frac{1}{2}$ hour 16 20
Each additional $\frac{1}{2}$ hour 5 40
(2) Helium and oxygen up to $\frac{1}{2}$ hour 16 20
Each additional $\frac{1}{2}$ hour 5 40
(3) Venethene, up to $\frac{1}{2}$ hour 10 80
Each additional $\frac{1}{2}$ hour 5 40
(4) Ethyl chloride, up to $\frac{1}{2}$ hour 10 80
Each additional $\frac{1}{2}$ hour 5 40
(5) Chloroform, up to $\frac{1}{2}$ hour 10 80
Each additional $\frac{1}{2}$ hour 5 40
(6) Curare 16 20

b Regional anesthesia

- (1) Spinal
(a) With or without supplement, up to $\frac{1}{2}$ hr 16 20
Each additional $\frac{1}{2}$ hour 5 40
(b) Continuous, up to $\frac{1}{2}$ hour 16 20
Each additional $\frac{1}{2}$ hour 5 40
(2) Local infiltration, with or without supplement, up to $\frac{1}{2}$ hour 16 20
(3) Nerve block, with or without supplement
(a) Minor (single nerve), up to $\frac{1}{2}$ hour 10 80
Each additional $\frac{1}{2}$ hour 5 40
(b) Major
(a) (Paravertebral) up to $\frac{1}{2}$ hour 16 20
Each additional $\frac{1}{2}$ hour 5 40
(b) Plexus, up to $\frac{1}{2}$ hour 16 20
Each additional $\frac{1}{2}$ hour 5 40
(4) Field block, with or without supplement, up to $\frac{1}{2}$ hour 16 20
Each additional $\frac{1}{2}$ hour 5 40
(5) Topical (permeation), up to $\frac{1}{2}$ hour 10 80
Each additional $\frac{1}{2}$ hour 5 40

c Intravenous anesthesia, with or without supplement

- (1) Pentothal Sodium, up to $\frac{1}{2}$ hour 16 20
Each additional $\frac{1}{2}$ hour 5 40
(2) Sodium Evipal, up to $\frac{1}{2}$ hour 16 20
Each additional $\frac{1}{2}$ hour 5 40

d Rectal anesthesia, with or without supplement

- (1) Tribromethanol in amylene hydrate (Avertin, fluid), up to $\frac{1}{2}$ hour 16 20
Each additional $\frac{1}{2}$ hour 5 40
(2) Paraldehyde, up to $\frac{1}{2}$ hour 10 80
Each additional $\frac{1}{2}$ hour 5 40
(3) Evipal Soluble, up to $\frac{1}{2}$ hour 16 20
Each additional $\frac{1}{2}$ hour 5 40
(4) Pentothal, up to $\frac{1}{2}$ hour 16 20
Each additional $\frac{1}{2}$ hour 5 40
(5) Ether-in-oil, up to $\frac{1}{2}$ hour 10 80
Each additional $\frac{1}{2}$ hour 5 40

e. Special techniques

- (1) Intratracheal anesthesia — up to $\frac{1}{2}$ hour (additional) 5 40
(2) Suction bronchoscopy 16 20
(3) Venoclysis 5 40

- (4) Transfusions 21 60
(5) Refrigeration 16 20

2 Chemical Pathology

a Bacteriological

- (1) Cultural examination for fungi 5 40
(2) Routine culture 2 16
(3) Pus or exudate, cultural examination, including classification of organism 5 40
(4) Throat culture, including classification of organism 5 40
(5) Blood culture 5 40
(6) Examination of smears 2 16

b Pathological

- (1) Autopsy 54 00
(2) Tissue examination, including smear for carcinoma 5 40
(3) Frozen section (rush diagnosis at laboratory) 10 80
(4) Frozen section (rush diagnosis at hospital) 27 00
(5) Guinea-pig inoculation 5 40

c Blood

- (1) Red count, white count, differential and hemoglobin 5 40
(2) Red count 2 16
(3) White count 2 16
(4) Differential 2 16
(5) Hemoglobin (Sahli) 2 16
(6) Platelet count 2 16
(7) Malarial parasites 5 40
(8) Bleeding and coagulation times 2 16
(9) Fragility test 5 40
(10) Sedimentation time 5 40
(11) Clot retraction 2 16
(12) Prothrombin time 3 24
(13) Hematocrit 5 40
(14) Grouping for transfusion 3 24
(15) Direct agglutination 5 40
(16) Aschheim-Zondek test 10 80
(17) Kahn test 3 24
(18) Hinton test (routine) 3 24
(19) Hinton test (rapid) 3 24
(20) Kolmer-Wassermann test 5 40
(21) Schwartz-McNeil test (complement-fixation test for gonorrhea) 5 40
(22) Heterophile antibody reaction 3 24
(23) Rh factor 5 40

d Blood chemistry

- (1) Albumin-globulin ratio 10 80
(2) Bromide 3 24
(3) Calcium 5 40
(4) Cephalin-cholesterol 3 24
(5) Chloride 3 24
(6) Cholesterol 6 48
(7) Carbon dioxide combining power 5 40
(8) Creatine 3 24
(9) Diastase 3 24
(10) Galactose-tolerance test 5 40
(11) Icterus index 2 16
(12) Nonprotein nitrogen 3 24
(13) Phosphatase, acid 5 40
(14) Phosphatase, alkaline 5 40
(15) Phosphorus 5 40
(16) Potassium thiocyanate 3 24
(17) Sugar 3 24
(18) Sugar and nonprotein nitrogen (same blood) 5 40
(19) Sulfonamide, concentrations 3 24
(20) Total protein 3 24
(21) Urea nitrogen 3 24
(22) Uric acid 3 24
(23) Van den Bergh 5 40

e Feces

- (1) Gross and microscopic (complete) 5 40
(2) Occult blood 2 16
(3) Fat 1 08
(4) Parasites 5 40

f Skin tests

- (1) Protein tests (each group of 25 proteins) 5 40
(2) Hay-fever test 5 40

mother in infant care and supervision of infant feeding)			b Myelography	37 80
		70 20	c Pelvis	10 80

			(3) 101 to 500 millicurie hours	86 40
			(4) 501 millicurie hours or more	139 40
			(5) Travel over 10 miles (add per mile)	1 08
			(6) Follow-up examination (each)	5 40
<i>Surgery</i>			1 Anesthesia (the practice of anesthesiology includes the preliminary preparation of the patient	

for anesthesia, supervision of premedication, selection of anesthetic agents and methods, the administration of anesthetic agents, the treatment of all complications pertaining to anesthesia during the operation and postoperatively and the treatment of certain medical conditions, such as pulmonary and other conditions requiring the services of an anesthesiologist — i.e. asphyxia, drug poisoning, caisson disease, asthma, convulsions, etc.)

a Inhalation anesthesia

(1) Ether — up to $\frac{1}{2}$ hour	10 80
Each additional $\frac{1}{2}$ hour	5 40
(2) Gas	
(a) Conventional	
(1) Nitrous oxide up to $\frac{1}{2}$ hour	10 80
Each additional $\frac{1}{2}$ hour	5 40
(2) Ethylene, up to $\frac{1}{2}$ hour	10 80
Each additional $\frac{1}{2}$ hour	5 40
(3) Carbon dioxide, up to $\frac{1}{2}$ hour	10 80
Each additional $\frac{1}{2}$ hour	5 40
(4) Oxygen, up to $\frac{1}{2}$ hour	10 80
Each additional $\frac{1}{2}$ hour	5 40
(b) Special	
(1) Cyclopropane, up to $\frac{1}{2}$ hour	16 20
Each additional $\frac{1}{2}$ hour	5 40
(2) Helium and oxygen, up to $\frac{1}{2}$ hour	16 20
Each additional $\frac{1}{2}$ hour	5 40
(3) Venethene, up to $\frac{1}{2}$ hour	10 80
Each additional $\frac{1}{2}$ hour	5 40
(4) Ethyl chloride, up to $\frac{1}{2}$ hour	10 80
Each additional $\frac{1}{2}$ hour	5 40
(5) Chloroform up to $\frac{1}{2}$ hour	10 80
Each additional $\frac{1}{2}$ hour	5 40
(6) Curare	16 20

b Regional anesthesia

(1) Spinal	
(a) With or without supplement, up to $\frac{1}{2}$ hr	16 20
Each additional $\frac{1}{2}$ hour	5 40
(b) Continuous, up to $\frac{1}{2}$ hour	16 20
Each additional $\frac{1}{2}$ hour	5 40
(2) Local infiltration, with or without supplement, up to $\frac{1}{2}$ hour	16 20
(3) Nerve block, with or without supplement	
(a) Minor (single nerve), up to $\frac{1}{2}$ hour	10 80
Each additional $\frac{1}{2}$ hour	5 40
(b) Major	
(a) (Paravertebral) up to $\frac{1}{2}$ hour	16 20
Each additional $\frac{1}{2}$ hour	5 40
(b) Plexus, up to $\frac{1}{2}$ hour	16 20
Each additional $\frac{1}{2}$ hour	5 40
(4) Field block, with or without supplement, up to $\frac{1}{2}$ hour	16 20
Each additional $\frac{1}{2}$ hour	5 40
(5) Topical (permeation), up to $\frac{1}{2}$ hour	10 80
Each additional $\frac{1}{2}$ hour	5 40

c Intravenous anesthesia, with or without supplement

(1) Pentothal Sodium, up to $\frac{1}{2}$ hour	16 20
Each additional $\frac{1}{2}$ hour	5 40
(2) Sodium Evipal, up to $\frac{1}{2}$ hour	16 20
Each additional $\frac{1}{2}$ hour	5 40

d Rectal anesthesia, with or without supplement

(1) Tribromethanol in amylene hydrate (Avertin, fluid), up to $\frac{1}{2}$ hour	16 20
Each additional $\frac{1}{2}$ hour	5 40
(2) Paraldehyde, up to $\frac{1}{2}$ hour	10 80
Each additional $\frac{1}{2}$ hour	5 40
(3) Evipal Soluble, up to $\frac{1}{2}$ hour	16 20
Each additional $\frac{1}{2}$ hour	5 40
(4) Pentothal, up to $\frac{1}{2}$ hour	16 20
Each additional $\frac{1}{2}$ hour	5 40
(5) Ether-in-oil, up to $\frac{1}{2}$ hour	10 80
Each additional $\frac{1}{2}$ hour	5 40

e Special techniques

(1) Intratracheal anesthesia — up to $\frac{1}{2}$ hour (additional)	5 40
(2) Suction bronchoscopy	16 20
(3) Venoclysis	5 40

(4) Transfusions	21 60
(5) Refrigeration	16 20

2 Clinical Pathology

a Bacteriological

(1) Cultural examination for fungi	5 40
(2) Routine culture	2 16
(3) Pus or exudate, cultural examination, including classification of organism	5 40
(4) Throat culture, including classification of organism	5 40
(5) Blood culture	5 40
(6) Examination of smears	2 16

b Pathological

(1) Autopsy	54 00
(2) Tissue examination, including smear for carcinoma	5 40
(3) Frozen section (rush diagnosis at laboratory)	10 80
(4) Frozen section (rush diagnosis at hospital)	27 00
(5) Guinea-pig inoculation	5 40

c Blood

(1) Red count, white count, differential and hemoglobin	5 40
(2) Red count	2 16
(3) White count	2 16
(4) Differential	2 16
(5) Hemoglobin (Sahl)	2 16
(6) Platelet count	2 16
(7) Malarial parasites	5 40
(8) Bleeding and coagulation times	2 16
(9) Fragility test	5 40
(10) Sedimentation time	5 40
(11) Clot retraction	2 16
(12) Prothrombin time	3 24
(13) Hematocrit	5 40
(14) Grouping for transfusion	3 24
(15) Direct agglutination	5 40
(16) Aschheim-Zondek test	10 80
(17) Kahn test	3 24
(18) Hinton test (routine)	3 24
(19) Hinton test (rapid)	3 24
(20) Kolmer-Wassermann test	5 40
(21) Schwartz-McNeil test (complement-fixation test for gonorrhea)	5 40
(22) Heterophile antibody reaction	3 24
(23) Rh factor	5 40

d Blood chemistry

(1) Albumin-globulin ratio	10 80
(2) Bromide	3 24
(3) Calcium	5 40
(4) Cephalin-cholesterol	3 24
(5) Chloride	3 24
(6) Cholesterol	6 48
(7) Carbon dioxide combining power	5 40
(8) Creatine	3 24
(9) Diastase	3 24
(10) Galactose-tolerance test	5 40
(11) Icterus index	2 16
(12) Nonprotein nitrogen	3 24
(13) Phosphatase, acid	5 40
(14) Phosphatase, alkaline	5 40
(15) Phosphorus	5 40
(16) Potassium thiocyanate	3 24
(17) Sugar	3 24
(18) Sugar and nonprotein nitrogen (same blood)	5 40
(19) Sulfonamide, concentrations	3 24
(20) Total protein	3 24
(21) Urea nitrogen	3 24
(22) Uric acid	3 24
(23) Van den Bergh	5 40

e Feces

(1) Cross and microscopic (complete)	5 40

EDITH E. PARRIS, *Assistant Editor*

CASE 32301

PRESENTATION OF CASE

First admission A sixty-three-year-old steam fitter entered the hospital because of hoarseness.

For years the patient had had a cough productive of small amounts of whitish sputum. A year before entry he began to notice intermittent attacks of hoarseness without accompanying dyspnea or hemoptysis. About the same time he also had a single bout of difficulty in swallowing. The hoarseness progressed for six months, remaining constant thereafter. He had lost about 15 pounds during the preceding two years.

The patient had always been well and strong except for an attack of "pneumonia" thirty years previously.

Physical examination revealed a moderately well nourished man. The larynx showed a thickened right vocal cord covered with whitish hyperkeratotic nodules extending toward the anterior commissure, where a soft polyp was visible. The left cord was slightly injected. The mobility of the larynx on swallowing was not impaired. There were a few, small, nontender cervical nodes. The mid-dorsal spine showed a moderate kyphosis. The chest was emphysematous, with increased anteroposterior diameter. One observer thought that it was slightly smaller on the left than on the right and that it lagged somewhat during respiratory movement. There were a few scattered rales over the left upper lung field. The diaphragm moved well. The heart appeared to be slightly enlarged, with both systolic and diastolic murmurs at the base and apex. The abdomen and extremities were normal.

The temperature, pulse and respirations were normal. The blood pressure was 108 systolic, 94 diastolic.

Examination of the blood showed a red-cell count of 3,980,000, with 12.2 gm. of hemoglobin, and a white-cell count of 5300, with 56 per cent neutrophils, 36 per cent lymphocytes and 6 per cent monocytes. The sedimentation rate was 30 mm. in thirty minutes, and 48 mm. in sixty minutes. Examination of the urine was negative.

An x-ray film of the chest revealed an area of infiltration in the left apex and considerable thickening in the left hilus. A sputum smear was negative for acid-fast organisms. A biopsy of the right vocal cord was reported as showing a Grade II epidermoid carcinoma. The patient was discharged to be readmitted for total laryngectomy.

Second admission (one month later) Another x-ray film of the chest revealed infiltration in both apexes that was interpreted as "probably active." Two sputum smears were negative for acid-fast organisms, but guinea-pig inoculation gave a positive reaction.

The patient was discharged to a sanatorium.

Third admission (three months later) Since the patient's tuberculosis was thought to have been arrested, he was admitted for total laryngectomy. Physical examination and x-ray study of the chest were essentially the same as on the previous admission. The operation was uneventful. The pathological report was Grade II epidermoid carcinoma, with metastases to regional lymph nodes.

The patient did well postoperatively, receiving 24,000 units of penicillin every three hours for thirteen days. On the fifteenth postoperative day, while sitting on the toilet, he was suddenly seized by an extremely severe pain in the epigastrium. He motioned for help, and while being assisted back to the ward, he collapsed on the floor. He was pale, writhing in pain and sweating profusely. When queried about the location of the pain, he repeatedly pointed to the epigastrium, chiefly in the midline. The lips had a grayish hue. He vomited a small amount of coffee-grounds material. Examination of the chest revealed only a few rhonchi at the left base. The heart had not changed since the previous examination. The abdomen was spastic throughout, particularly in the epigastrium. There was also exquisite rebound tenderness throughout, most marked in the left upper quadrant and midepigastrium, and referred from the right lower quadrant to below the xiphoid. Peristalsis was absent. No masses could be made out. There was no arm, shoulder, chest or neck pain. Pain was not increased by respiration, and there was no cough. When asked specifically, the patient denied that there was an element of substernal compression, tightness in the chest or difficult breathing. It was deduced by devious questioning — to which he could only indicate assent or negation — that the pain was constant, unremitting, nonradiating and of great severity, that it was unassociated with a desire to urinate or defecate and that its location was strictly in the upper abdomen.

Examination of the blood showed a white-cell count of 16,100. A stool specimen obtained during rectal examination was guaiac positive.

An x-ray film of the chest showed mottled areas of increased density in both lower lung fields, in addition to calcified areas at the apexes. The vascular

shadows were prominent in both hilar regions, and there appeared to be some haziness in the right upper mediastinum. The abdomen showed no evidence of dilated loops. There was a small amount of gas and much fecal material in the large bowel.

An electrocardiogram showed evidence of chronic coronary disease but none of an acute process.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. OLIVER COPE Of course, from the record, only one thing can explain the situation. The patient had an operation and survived. The one lesion that fits with that history is a perforated peptic ulcer. That diagnosis may be too easy, and therefore I had better see the x-ray films.

DR. JAMES R. LINGLEY These first two films, taken at the Eye and Ear Infirmary one month apart, show emphysema and a process at the apex on both sides, more extensive on the left than on the right. It is a hazy type of infiltration. This film, taken just before the abdominal operation and fifteen days following laryngectomy, shows a high diaphragm on both sides and density at both bases, which could be explained by atelectasis from a high diaphragm, and the same process in the apexes. The film of the abdomen shows extensive calcification of the abdominal aorta and the internal iliac arteries. There is an area of calcification over the upper pole of the left kidney, which is interesting in view of the findings in the chest. Unfortunately, we do not have a lateral view, so that I cannot be sure that it is a calcified adrenal gland, in the anteroposterior view the calcification is in the proper position for it, but the explanation may be an overlying calcified lymph node.

DR. COPE They should have written that into the record to make it harder. Is there any evidence of air under the diaphragm?

DR. LINGLEY Since the films were taken in a prone position, I cannot rule out air under the diaphragm.

DR. COPE I say that this was a perforated lesion of the upper gastrointestinal tract because that complication occurs not too infrequently following a major surgical procedure — often enough to be something of which everyone should be aware. The pain, of course, was not typical of anything other than severe irritation, and it may turn out that the patient had a ruptured aortic aneurysm. I assume that he made some effort at the toilet, which was the final push that ruptured something. Effort to defecate could result finally in perforation somewhere in the intestinal tract. Such effort could rupture an abscess or could be the initiating cause of rupture of an aneurysm or of rupture through a weak place somewhere along the aorta. The upper abdominal pain is the typical place for pain to radiate in rupture of the thoracic aorta. Usually, at least in the few patients I have had an opportunity to see in the

differential diagnosis of a surgical lesion, the pain starts not so abruptly, developing quite quickly to a high pitch, however. I shall exclude dissecting aneurysm of the aorta as a diagnosis, because in all probability the patient would not have survived it.

Abdominal tenderness and pain in the epigastrium can of course be produced by a lesion in the chest in the region of the sixth to ninth costal nerves. One can be misled by a lesion in the chest, the abdomen has often been opened for disease above the diaphragm. On the other hand, peristalsis was absent, and there was coffee-grounds material in the stomach, with a positive guaiac test in the stools, which suggest that the lesion was within the gastrointestinal tract. Also, the x-ray studies are not compatible with an abscess of the lung. I have never seen a tuberculous abscess rupture down through the diaphragm. There is only one infectious disease that does go down through the diaphragm — actinomycosis. Subdiaphragmatic abscesses frequently rupture upward through the diaphragm into the chest, but the reverse is rare, except in actinomycotic lesions, actinomycosis being no respecter of anatomic barriers. Tuberculosis, on the other hand, is a respecter of anatomic partitions and does not go downward ordinarily, I shall exclude tuberculosis of the lungs as the cause of this acute painful episode, on the basis of this last chest film, which I interpret as negative so far as the lungs are concerned, and also on the findings related to the abdominal organs.

What about the primary diagnosis that I mentioned — a perforated peptic ulcer? From the history the man had had no ulcer symptoms or indigestion, but the latter might have been missed because of the fact that after laryngectomy there is a problem in feeding and that with any symptoms referable to an acute ulcerative process in the stomach and duodenum, the upper small intestine might easily be missed. Various symptoms have been overlooked in such complicated feeding problems. Acute ulcer of the upper gastrointestinal tract, so-called "peptic ulcer," is not an infrequent lesion following trauma of various sorts. The classic description is Curling's ulcer, the type that follows burn trauma. It also follows other kinds of trauma and acute adrenal insufficiency. Because of the latter I wonder why the finding of the X-ray Department was not recorded, the presence of calcification in an adrenal gland suggests old tuberculous damage. The patient might well have had some degree of adrenocortical insufficiency or failure to respond to operative treatment in a way that would result in what one might call subclinical shock, which could have been the initiating factor of the ulcer. This type of ulceration has received a great deal of attention recently regarding the so-called "alarm reaction,"* which occurs with hemoconcentration, and this man may have had hemoconcentration following laryn-

*Selye, H. General adaptation syndrome and diseases of adaptation. *J. Clin. Endocrinol.* 6:117-230, 1946.

gectomy He had chronic tuberculosis of the lung, which may have prevented a good response to treatment like that of a healthy vigorous person, he had two strikes against him to begin with

I have stuck my neck out a long way I have even gone prematurely into a historical account of acute gastrointestinal ulcer following trauma, but I have done so because I do not see any other alternative I should expect the ulcer that perforated to have been in the stomach or, more probably, in the duodenum It may have been multiple Dr Castleman, you will recall that you and Dr John Bradley had a case several years ago in which on the eighth postoperative day one ulcer perforated at 2:00 a m, a second at 4:30 a m and later a third, which was not recognized clinically but which was found at post-mortem examination Multiple ulcers are a possibility in the case under discussion

DR BENJAMIN CASTLEMAN Are there any comments or other suggestions?

DR WALTER BAUER A perforated peptic ulcer is a likely explanation of the episode of acute pain

DR CASTLEMAN Dr Dahl, will you tell us what your impression was?

DR LEWIS K DAHL From the medical standpoint we went through approximately the same process of reasoning as that of Dr Cope We favored a vascular accident rather than a perforated viscus We thought that the only hope of survival lay in the possibility of a perforated viscus and therefore believed that operation was indicated I think that the surgical men favored a perforated viscus, but it is fair to say that no one considered the actual condition

CLINICAL DIAGNOSIS

Perforated peptic ulcer

DR COPE'S DIAGNOSES

Perforated peptic ulcer

Chronic pulmonary tuberculosis

ANATOMICAL DIAGNOSIS

Negative abdominal exploration

PATHOLOGICAL DISCUSSION

DR CASTLEMAN The abdominal exploration was entirely negative You may have another chance, Dr Cope

DIFFERENTIAL DIAGNOSIS (Continued)

DR COPE The medical side passed it up, and the thing I want to stress again is that the patient survived That is what puzzles me It is not in the record, but I assume that the patient survived the operation as well as the lesion that gave rise to the pain

DR CASTLEMAN The patient did die — about twenty-four hours after operation

DR COPE That makes it somewhat easier because, as I said at the outset, the only curable lesion

that I could think of was a perforated peptic ulcer, which was sutured at operation, but I cannot imagine survival with a dissecting aneurysm of the aorta I suppose that the patient could have survived, but this came on acutely and I suspect that it eventually led to death I do not know enough about that, however

To go back to the tuberculosis, there was undoubtedly active tuberculosis in the chest I can not believe that there was a rupture of an abscess, with formation of empyema There was no displacement of the mediastinum, no cough and no increase in pain on respiration The record also does not suggest that an abscess had ruptured into a bronchus In other words, I do not find evidence of an abscess that broke into a pleural space I can find nothing pointing to the abdomen, and that is substantiated by the fact that the abdominal laparotomy was negative I cannot go any farther with tuberculosis of the lung

A negative electrocardiogram at such a stage, if my understanding is correct, does not exclude a coronary infarction The electrocardiographic changes may not become positive (I hope that I shall be corrected if I am making a wrong statement) for three or four days or possibly longer This could have been coronary occlusion, because absence of the left arm radiation and absence of substernal tightness or compression do not exclude a coronary lesion I must go back to a vascular lesion to explain this episode, and I do not know whether it was a lesion of the aorta — a dissecting aneurysm of the thoracic aorta — or a coronary accident

DR CASTLEMAN The field is still wide open

DR COPE Dr Bauer, you must have an opinion on this

DR BAUER I am stumped

DR COPE I am glad we have that in the record

CLINICAL DIAGNOSIS

Gastrointestinal hemorrhage, cause undetermined
Pancreatitis?

DR. COPE'S DIAGNOSIS

Dissecting aneurysm of aorta?

Coronary thrombosis?

ANATOMICAL DIAGNOSES

Acute fibrinopurulent mediastinitis

Acute fibrinopurulent pleuritis

Chronic pulmonary tuberculosis

Carcinomas of stomach and sigmoid

Chronic tuberculosis of left adrenal gland, with calcification

Operation total laryngectomy for epidermoid carcinoma of larynx

PATHOLOGICAL DISCUSSION

DR CASTLEMAN Before I call on Dr Schall to discuss the operation, let me tell you what was found

at autopsy Surrounding the posterior aspect of the esophagus from about the fourth to the eighth thoracic vertebra, we found an acute mediastinitis, there was about 150 cc of foul-smelling fibrino-purulent material This surrounded the posterior aspect and both sides of the esophagus and extended into both pleural cavities We found 700 cc of purulent fluid in the left chest This abscess of the posterior mediastinum extended downward forming a channel into the right pleural cavity It also extended upward, but not so far up as the tracheotomy There was no connection between the tracheotomy and this infection of the posterior mediastinum We asked Dr Schall about this complication of laryngectomy, and he is here to tell us about it

DR. LEROY A SCHALL The fatal complications of total laryngectomy are hemorrhage and sepsis The sulfonamides and the antibiotics have practically eliminated infection as a complication, and this is the first case of serious infection since the introduction of these agents In 106 cases of total laryngectomy, death occurred in only 3 cases, including this one, from infection Our patients are put on 24,000 units of penicillin every three hours With this patient penicillin was given for twelve days Clinically he did exceptionally well His temperature was normal, the wound healed by first intention, and he was about ready to be discharged

I believe that it is important in doing a laryngectomy to avoid, so far as possible, opening the fascial planes to the mediastinum The posterior attachment of the trachea to the esophagus is not disturbed For this reason I do not do the so-called "pull-through" operation, whereby the trachea is freed and pulled through a buttonhole incision

You may well understand that many patients with cancer of the larynx are poor surgical risks This patient's tuberculosis delayed the operation

The lesson in this case was that of infection masked by penicillin

DR. CASTLEMAN There was no evidence of tuberculosis in the mediastinum, although tuberculosis in the lungs was still quite active There was calcification of the left adrenal gland, due to old tuberculosis Following operation a gastric hemorrhage occurred, which proved to be due to carcinoma of the stomach, there was also a carcinoma of the sigmoid

DR. COPE I gambled on the knowledge of Dr Schall's excellent operative record, but I should have considered mediastinitis on the basis of the x-ray film

DR. LINGLEY There is nothing distinctive in that film There was a high diaphragm which is consistent with mediastinitis

DR. BAUER There is not much in the record to suggest sepsis

DR. SCHALL Nor was there any history of sepsis

DR. CASTLEMAN Would you agree on the apparent masking of the infection by the penicillin?

DR. BAUER Yes The penicillin was stopped on the thirteenth day, and the episode occurred on the fifteenth day There was nothing in the history to indicate the presence of infection, and I also thought that the subsequent widening of the mediastinum was due to a high diaphragm That was consistent with Dr Cope's original diagnosis If I had discussed the case I still should have made the same diagnosis as Dr Cope did — perforated peptic ulcer — and obviously should have been wrong

CASE 32302

PRESENTATION OF CASE

A sixty-five-year-old widow entered the hospital because of severe dyspnea

For over a year the patient had had a chronic cough productive of thin sputum, which was never bloody She was also thought to have lost some weight Five weeks before entry she consulted a physician because of these symptoms She was found to be emaciated, weighing 101 pounds X-ray study showed the heart to be enlarged, and an aortic diastolic murmur was heard Some inflammation of the throat and larynx was present, but there was no x-ray evidence of pulmonary disease The blood pressure was within normal limits, and the urine was normal A week before entry the patient noted swelling of the ankles, and three days later she appeared so thin and exhausted that she was put to bed Her physician prescribed aminophyllin tablets She began to cough up heavy yellowish sputum and ran a temperature ranging between 99 and 101.6° She also complained of discomfort along the right costal margin on coughing, but she had no chills and no sharp pain intensified by inspiration About twenty-four hours before entry she became progressively more dyspneic

On physical examination, the patient was somewhat pale, emaciated and markedly dyspneic, with moderately cyanotic lips and audible tracheal rales She spoke in almost unintelligible snatches between breaths and appeared somewhat confused Most of the history had to be obtained from a companion She was in no greater discomfort when lying on her side or with her back at 30° than when sitting upright The left pupil was somewhat larger than the right, and both pupils appeared slightly irregular The heart was enlarged, the area of dullness extending to the midaxillary line on the left The sounds were strong but partially obscured by loud respiratory noises No murmur or gallop rhythm was made out The radial pulses were weak and thready, with occasional irregularities The chest showed restricted expansion on the right There was dullness to flatness on percussion over the right

lower lung field both anteriorly and posteriorly. Coarse, moist rales were heard throughout the other portions of the chest. The upper abdomen was markedly resistant to palpation, but there was apparently no tenderness and no masses were made out. The extremities were somewhat weak, and there was ++ pitting edema over the lower legs.

The temperature was 100.5°F, the pulse 140, and the respirations 25. The blood pressure was 105 systolic, 70 diastolic.

Examination of the blood showed a white-cell count of 43,200, with 90 per cent neutrophils and a marked shift to the left. No toxic granules were seen. The platelets and red cells appeared normal. Blood cultures were negative. The urine had a specific gravity of 1.020 and showed a + test for albumin, the sediment contained many bacteria and 10 white cells per high-power field.

The patient was given Cedilanid and oxygen, and tourniquets were applied with considerable clearing of the moisture in the left chest and recession of the cardiac apex to the anterior axillary line. Nevertheless she gradually lapsed into shock and stupor. Neo-Synephrine had no appreciable effect on the blood pressure. The respirations became progressively shallower and slower. She died eleven hours after admission.

DIFFERENTIAL DIAGNOSIS

DR. JOHN GRAHAM It seems obvious to me that, whatever else this patient had, she had heart disease. This is attested to by two sets of significant findings, — those of x-ray examination and those of physical examination, — both of which indicated that the heart was enlarged. The other symptoms, such as dyspnea, edema and cough, can conceivably be attributed to other diseases, but that much enlargement of the heart in the absence of severe anemia — and we are told that the red cells appeared normal — indicates serious heart disease. The question in this case is whether there was some lesion in addition to the heart disease.

Several factors suggest that more than cardiac disease was present. The cough with thin sputum might have been consistent with cardiac disease alone. X-ray examination was negative, so far as the lungs were concerned. When she really began to get sick, however, just before coming to the hospital, she began bringing up thick yellow sputum and at the same time began to have a fever as high as 101.6°F and pain in the right chest. On physical examination she had dullness and flatness throughout the right chest, with limited motion and some pain, and dyspnea in all positions. These facts are not particularly characteristic of cardiac decompensation and suggest a further cause for the dyspnea and cough. When treatment for congestive failure was given, the signs in the left chest cleared fairly well but the findings in the right chest were not improved.

The white-cell count was 43,000, with 90 per cent neutrophils and a marked shift to the left, which is suggestive of acute infection. One wonders if the patient had leukemia, but there is no indication that there were any really young cells or any enlargement of the lymph nodes, liver or spleen, although examination of the abdomen was rather difficult. I shall exclude that possibility and take the high white-cell count with the high percentage of neutrophils and the shift to the left as an indication of acute infection. In other words, I am inclined to think that an acute infectious process was going on in the chest, which was possibly an added complication to the existing cardiac condition.

As for the pulmonary infection, one wonders about bronchiectasis, with a history for a year. Opposed to that are the completely negative lung fields by x-ray study and the fact that five weeks before admission the sputum was not particularly characteristic. One wonders about carcinoma obstructing a bronchus, with infection beyond the obstruction. Again the negative x-ray findings argue against that possibility. With sudden and complete signs developing rather quickly, one wonders about lung abscess, which can be excluded, however the sputum was not characteristic, and there was no suggestion of the signs and symptoms that are apt to precede a lung abscess. One wonders about an infarct, but with an infarct that gave so many signs in the chest over such a large area one would expect bloody sputum and a more sudden collapse than this story implies. It is much more probable that this patient had beginning congestive failure, with a superimposed acute infection of the lungs — a pneumonitis of one sort or another — and, possibly, some fluid in the pleural space. I rather think that the pneumonia was the final straw that broke the camel's back.

That brings up the question of the heart lesion, whose nature depends somewhat on the findings given. For instance, we are told that five weeks before entry, on examination by an outside physician, an aortic diastolic murmur was recorded. Later, on admission to the hospital, no murmurs were heard. It is important to realize that at that time the record goes out of the way to say that the patient had a noisy chest and rapid pulse (140) and was in a critical state. A definite aortic diastolic murmur was probably heard when there was a good opportunity to listen to the heart under normal conditions. I therefore believe that the heart was enlarged, with aortic regurgitation.

When these facts are put together one is led to consider three main types of heart disease. The first is rheumatic heart disease, with aortic regurgitation, but such a lesion would probably have caused trouble before the age of sixty-five. One might suppose that the whole picture was explained by an acute attack of rheumatic fever, unusual but

still possible in older people, superimposed on an already damaged rheumatic heart, but such an explanation is unlikely statistically. The second type is hypertensive arteriosclerotic heart disease, in which aortic regurgitation is sometimes found with dilatation of the heart. To be sure, the patient had no hypertension during the time she was observed, but we know that such patients may have a low blood pressure when the heart begins to fail. I am inclined to discard that diagnosis because one finding suggests a third type of heart disease, namely, syphilitic heart disease. To be sure syphilitic heart disease is more usual in the forties and fifties, but it does occur in the sixties and seventies. It is about five times as frequent in men as in women. There are some things, however, in favor of syphilitic heart disease in this case. The patient had a cardiac condition that progressed to death in the course of a year from the time it was first noted or from the time of the first symptoms. She had an aortic diastolic murmur, which is consistent with syphilitic aortitis, and she died of cardiac asthma or pulmonary edema, which is a characteristic end in syphilitic heart disease. She also had unequal and irregular pupils. There is a definite association between central-nervous-system and cardiovascular syphilis. I believe that 10 to 20 per cent of the people with cardiovascular syphilis also have central-nervous-system syphilis. What the percentage is in the reverse situation, I do not know. I think that this patient had syphilitic heart disease, although we are not given the results of a blood Hinton test. Having decided that, one can ask whether an aneurysm developed and blocked off a bronchus to produce the chest findings. In view of the negative x-ray study for aneurysm five weeks before entry, it is too much to suppose that an aneurysm of these proportions would have developed within the short time before the patient entered the hospital. One can wonder about coronary closure, which occurs in syphilis at the mouth of the coronary artery, but preceding this attack of failure there was no history of pain and coronary closure is therefore unlikely.

I shall conclude by making the following diagnoses: syphilitic heart disease, with aortic regurgitation, cardiac decompensation, with pulmonary edema, right pleural effusion, possibly secondarily infected, pneumonitis in the right lower and middle lobes, and syphilis of the central nervous system.

DR WILLIAM D SMITH This patient was sent to me in my office almost five weeks before she came to the hospital. The history was interesting because the only complaint was cough, which was at first paroxysmal, occurred mostly in the morning and had grown steadily worse until, for two weeks, it had kept her awake almost all night, in spite of the fact that she was taking cough medicine, which her own physician had given her. Another interesting thing was that two months before admission she had

a wheeze, which persisted for two weeks and ended in a tremendous paroxysm of cough in which she raised a small hard mass of something that nobody could identify.

DR WALTER BAUER Was the wheeze bilateral?

DR SMITH I do not know about that. She said that about two months previously she wheezed almost constantly but the wheezing ceased after the coughing paroxysm, with the extrusion of the small hard lump. So far as the heart is concerned she had no failure at the time I saw her, although she did have a moderately enlarged heart. She had a systolic and an early blowing diastolic murmur at the apex. The heart rate was regular, and she had no signs of chronic passive congestion and never admitted any shortness of breath, except during the paroxysm of cough.

I could not find anything in the chest. She coughed a great deal in the office—it was a dry hard cough. We tried to get sputum and did get an infinitesimal amount of mucus. She had been checked two or three weeks earlier at another hospital, but in spite of the fact that she had had an x-ray examination three weeks before I saw her, I had another x-ray film taken, which was negative. Because of the hoarseness, which I supposed was due to chronic cough, I had a nose-and-throat man examine the larynx and trachea, which he reported showed only extreme redness. The blood pressure was within normal limits, and the urine was normal. My opinion was that, in addition to the heart that had given no symptoms, the patient almost surely had disease of the lung. I wanted her to come in to the hospital for further study, but she went to Philadelphia to visit her sister, and the next time that I heard from her, her physician telephoned that she was in cardiac failure, she was sent to the hospital in a moribund condition. I thought that she must have had some lung disease that had not been discovered. She had no pain in the chest and no hemoptysis.

DR BAUER She had an aortic murmur.

DR SMITH Yes. The heart was moderately enlarged. She had a systolic murmur at the apex and a rather faint but definite early aortic diastolic murmur, which I could hear at the apex much better than elsewhere.

DR GRAHAM I am impressed with the first-hand description of the cough. It seems to me to have been a much more prominent feature for a longer time than I had gathered from the record. I am also impressed by the fact that if it had been on a cardiac basis Dr Smith would have detected more evidence of cardiac failure at the time he saw the patient. The degree of cough is the most striking thing he described and raises the question whether this patient had adenoma of the bronchus, which did not show in the x-ray film but finally plugged the bronchus and gave rise to a secondary infectious process.

CLINICAL DIAGNOSES

Arteriosclerotic heart disease, with congestive failure
 Pulmonary edema and right pleural effusion
 Bronchopneumonia, extensive

DR GRAHAM'S DIAGNOSES

Syphilitic heart disease, with aortic regurgitation
 Congestive heart failure
 Chronic pneumonitis, right
 Pleural effusion
 Central-nervous-system syphilis?

ANATOMICAL DIAGNOSES

Empyema, right.
 Lung abscess, right lower lobe
 Chronic pneumonitis, right lower lobe
 Broncholiths, with ulceration of right and left bronchi
 Tuberculosis, calcified, of bronchial lymph nodes
 Traction diverticulum of esophagus

PATHOLOGICAL DISCUSSION

DR BENJAMIN CASTLEMAN Autopsy showed empyema of the right pleural cavity—1200 cc of foul-smelling purulent material. In removing most of this fluid we discovered that it had developed from a small abscess in the right lower lobe. The abscess was rather well defined, measuring 2 to 3 cm in diameter. Around the abscess, involving the greater part of the right lobe, was a chronic pneumonitis. The remaining lobes, which appeared perfectly normal, were not congested to any extent.

The interesting thing about this case is the cause of the lung abscess. Scattered over the mucosa of the

lower trachea and both bronchi were about five or six irregular foci of black anthracotic pigmentation. These areas were closely related to calcified anthracotic mediastinal lymph nodes adherent to the wall of the trachea and bronchi, and in each bronchus just beyond the carina a calcified node had eroded through the mucosa and presented in the lumen. The larger protruding calcified mass measured about 1 cm in diameter. We were unable to find a calcified mass in the abscess. Perhaps the mass that produced the abscess was the one the patient coughed up. I believe that the chronic pneumonitis and abscess originated from one of these so-called "broncholiths."

We were unable to find any evidence of active tuberculosis anywhere. There were scars at the apexes, evidence of old tuberculosis, and the regional nodes showed calcification. The calcified lymph nodes had also produced a traction diverticulum of the esophagus.

The heart was not remarkable; it weighed only 325 gm, the valves were normal, and coronary arteries showed extremely little sclerosis.

DR BAUER There was no evidence of valvular disease?

DR CASTLEMAN No.

A PHYSICIAN That does not explain the inequality of the pupils.

DR CASTLEMAN We did not examine the head.

It is strange that nothing was discovered in the right lower lobe when the patient was examined five weeks previously, because the pneumonitis was chronic. Many of the bronchi were plugged with connective tissue reminiscent of bronchiolitis fibrosa obliterans, and some of the small arteries in that region were plugged with thrombi such as one might see in an old infection.

THE TREATMENT OF BACTERIAL MENINGITIS

THERE is a general impression among a great many physicians that the recent introduction of potent antibacterial agents, including the sulfa drugs and particularly penicillin, has rendered bacteriologic diagnosis unnecessary and obsolete. This impression is fostered and strengthened by the necessity for the early use of these agents to obtain the optimum effect in the treatment of infections and also by the fact that cultural results are so often meaningless if materials are obtained for examination after these forms of antibacterial therapy have been given for any length of time. The fallacies in this reasoning and the practical importance of early and proper bacteriologic diagnosis of infections prior to treatment with modern chemotherapeutic

and antibiotic agents are most strikingly illustrated in a group of the most serious infectious diseases, namely, the bacterial meningitides.

Elsewhere in this issue of the *Journal* there is a report of the treatment of 9 cases of *Haemophilus influenzae* meningitis. In 7 of these cases, cure of this infection was attributable solely to the use of the new antibiotic streptomycin. The results in these cases and the experience of others in similar cases seem to justify the conclusions that at the present time streptomycin is the best treatment for this type of meningitis and that the antibiotic should be given both intrathecally and intramuscularly.

Prior to the introduction of streptomycin, comparable results were obtained in cases of meningitis caused by Type B strains of *H. influenzae* by the use of specific rabbit antiserum supplemented by sulfonamides. This form of treatment should still be considered as a useful alternative when streptomycin is not available or when treatment with the antibiotic is not effective. The latter possibility may prove to be an important and serious one because the development of resistance or "fastness" during the course of treatment of infections due to organisms that were originally susceptible to streptomycin has already been encountered more frequently with this antibiotic than with any of the other antibacterial agents now in use.

Two of the 9 reported cases of *H. influenzae* meningitis were complicated by severe *Staphylococcus aureus* infections, which occurred after the patients were completely free of *H. influenzae*. It was necessary to resort to full doses of penicillin for the treatment of these staphylococcal infections and a cure was effected in one of the cases by such therapy. The fact that recovery would probably not have occurred without penicillin in this case is further proof of the usefulness of bacteriologic studies. The data derived from bacteriologic studies are therefore useful not only in determining the optimum therapy but also, together with the clinical findings, in helping to establish the causes of failure.

Thus it has been shown that meningococcal meningitis is best treated by parenteral or oral sulfonamides and that penicillin is probably unnecessary, although it may be used as an adjunct in severe bacteremic cases. Penicillin alone, even when

given parenterally and intrathecally, has frequently been found to be inferior to sulfonamides in cases of meningococcal meningitis. In cases of hemolytic streptococcus infection the sulfonamide drugs alone may also be adequate. In such cases, however, there seems to be more justification for the use of penicillin because of the marked sensitivity of most strains of hemolytic streptococci to penicillin and because of the recent increase in the number of sulfonamide-resistant strains of this organism. Cases of pneumococcal and staphylococcal meningitis require the combined use of sulfonamides and penicillin, the latter being given both parenterally and intrathecally. The necessity for this combined treatment is based on the reported results in clinical cases and also has some experimental basis. Meningitis due to gram-negative bacilli usually does not respond well to treatment with sulfonamides alone, and penicillin generally has no effect whatever in these cases. Streptomycin given parenterally and intrathecally offers the best hope in such cases, although proof of the value of this agent in meningitis is not yet available except in cases due to *H. influenzae*. The necessity for intrathecal therapy with streptomycin, as with penicillin, is based on the poor penetration of these antibiotics into the cerebrospinal fluid. The duration of treatment is also dependent on the causative agent and varies from a brief period of perhaps two or three days after sterilization of the spinal fluid in cases of meningococcal meningitis to as long as three weeks or even longer in cases of staphylococcal meningitis.

In addition to these pyogenic infections of the meninges, cases of syphilitic meningitis have now been shown to respond to treatment with penicillin. Parenteral therapy is adequate, intrathecal therapy not only being unnecessary but also often resulting in serious reactions. There is also one case of apparent recovery following systemic and intrathecal treatment with streptomycin in a proved case of tuberculous meningitis.*

The best practical procedure to be followed when one is confronted with a clinical case of meningitis is to obtain the materials for bacteriologic study as soon as the diagnosis is made or suspected. One

may then proceed immediately with therapy along the lines suggested by the likeliest clinical diagnosis. A change to the optimum treatment is then made after the etiologic diagnosis is established from the cultures of the blood or spinal fluid. The proper choice of antibacterial agent, dosage and route and duration of therapy, as well as the prognosis, all depend on the etiologic diagnosis. Further cultural studies are indicated in following the course of the infection, particularly when the response of the patient, as judged from the clinical and laboratory observations, seems inadequate.

THE FIRST DESCRIPTION OF RICKETS

Just over three hundred years ago, in 1645, a young man, formerly a student at Merton College, Oxford, finished a course of medicine at the University of Leyden and was given a medical degree. As usual, he was required to write a graduation thesis. This was read in Latin before his examiners at Leyden on October 18, 1645, by Daniel Whistler, then twenty-five years of age. In the title he used the English word "rickets," thus publishing for the first time, so far as is known, the name that the disease still bears. It is not quite clear where this name came from. Whistler stated that the disease had been observed in England for at least twenty-five years and that the name was said to have been taken from the surname of a quack who was the first to treat the condition. Others have pointed out that this fanciful name arose in the county of Dorset, where those who are short of breath are said, in the dialect of the district, "to rucket." Wherever the name originally came from, the addition of it to medical literature is due to the medical student, Daniel Whistler.

Whistler's description of the disease is a concise and clear statement of most of the then known facts and, according to Still,¹ appears to have been based on personal observations. As Whistler did no post-mortem examinations, his description of the pathology of rickets is purely speculative. Still believes that Whistler may have known of the incomplete description of rickets published by Reusner in 1582, but Whistler's description was almost certainly the result of personal contacts with patients and not

*Cooke, R. E., Dunphy, D. L., and Blake, F. G. Streptomycin in tuberculous meningitis: report of its use in one-year-old infant. *Yale J Biol & Med* 18:221-226, 1946.

imply the copying of material from a previous author

The thesis had little influence on the development of knowledge of this condition, for it was not until Francis Glisson and a committee of seven at the Royal College of Physicians in London investigated the disease and published their report in 1650 that rickets was accepted as a clinical entity

Whistler's later career was not a happy one After returning to London from Leyden, he received his medical degree at Oxford in 1647 and became a fellow of the College of Physicians two years later He then practiced medicine in London, but his interests were widespread since he taught geometry at Gresham College and served as a Linacre Reader at Oxford Whistler served as a naval surgeon and later traveled in Sweden Honored by being elected as the Harvey Orator in 1659, he ultimately rose to the office of treasurer and finally that of president of the College of Physicians Both Samuel Pepys and John Evelyn, the diarists, were friends

It was toward the end of his life that Daniel Whistler got into difficulties, and after his death Munk,² the historian of the Royal College of Physicians, wrote "Whistler's character will not bear examination, and it would have been well for the interest of the College had he not admitted to some, at least, of the places of trust he was elected to fill His manners were agreeable and he shone particularly in society, yet it is but too evident that duty, honor and probity weighed but lightly with him" He apparently handled the financial matters of the College of Physicians badly and probably misappropriated some of the funds He is said to have married a rich widow His extensive practice in London brought him in a thousand pounds a year, a large sum for the middle of the seventeenth century, and yet he died in debt, with a blot on his name, which cannot be erased even after three hundred years He should be remembered, however, for his account of rickets, which established the name of the disease, although at the time his medical thesis from the University of Leyden attracted little attention Whistler, no doubt, resented this, particularly since so much recognition had been given to Glisson, as a result he had his thesis reprinted in London in 1684, shortly before his death

MISCELLANY

NOTES

The following appointments to the teaching staff of Harvard Medical School have recently been announced Frank Dennette Adams, of Boston (Lit B Princeton University 1915, M.D. Harvard University 1917), instructor in medicine, Marshall Kinne Bartlett, of Dedham (A.B. Yale University 1924, M.D. Harvard University 1928), instructor in surgery, Joseph Henry Bragdon, of Milton (A.B. Yale University 1935, M.D. Columbia University 1939), instructor in pathology, Joseph Messer Clough, of New London, New Hampshire (A.B. Dartmouth College 1931, M.D. Jefferson Medical College 1936), assistant in ophthalmology, David Wesley Compton, of Vashon, Washington (S.B. University of Washington 1937, M.D. University of Pennsylvania 1941), assistant in anesthesia, Geoffrey Edsall, of Cambridge (M.D. Harvard University 1934), instructor in bacteriology and immunology, Milton Elkin, of Andover (A.B. Harvard University 1937), M.D. Harvard University 1941, assistant in medicine, Robert Goldstein, of Dover, New Jersey (A.B. Princeton 1935, M.D. Harvard University 1937), assistant in medicine, James Hutcheson Graham, of Westmount, Quebec (M.D.C.M. McGill University 1942), assistant in medicine, William Frederick Greenwood, of Toronto, Ontario (M.D. University of Toronto 1937), research fellow in physiology, Lorne Edward Hackworth, of Sheffield, Alabama (S.B. Florence, Alabama, State Teachers College 1936, S.M. University of Alabama 1938, M.D. Harvard University 1945), assistant and Arthur Tracy Cabot Fellow in Surgery, George Kelemen, of Boston (M.D. University of Budapest 1915), instructor in otology, Wiland Fenway Leadbetter, of Needham (S.B. Bates College 1928, M.D. Johns Hopkins University 1932), assistant in genitourinary surgery, Arthur Paige Long, of Needham (S.B. University of Iowa 1932, M.D. University of Iowa 1934, M.P.H. Harvard University 1937, D.P.H. Harvard University 1938), instructor in bacteriology and immunology, Charles Pearson Lyman, of Brookline (A.B. Harvard University, 1936, A.M. Harvard University 1939, Ph.D. Harvard University 1942), research fellow in anatomy, Alexander Marble, of Boston (A.B. University of Kansas, 1922, A.M. University of Kansas 1923, M.D. Harvard University 1927), instructor in medicine, Edward Meilman, of Roxbury (A.B. Harvard University 1936, M.D. Harvard University 1940), assistant in medicine, Tom Fite Paine, Jr., of Aberdeen, Mississippi (S.B. Vanderbilt University 1939, M.D. Vanderbilt University 1942), research fellow in medicine, George Pike, of Roxbury (A.B. Harvard University 1932, M.D. Harvard University 1936), assistant in medicine, Eugene Edwin Record, of Boston (S.B. Harvard University 1932, M.D. McGill University 1937), assistant in orthopedic surgery, Carter Redd Rowe, of Fredericksburg, Virginia (A.B. Davidson College 1928, M.D. Harvard University 1935), assistant in orthopedic surgery, Earl Spinks Scale, of Boston (M.D. Tulane University 1935), assistant in ophthalmology, Gerald Shortz, of Kendallville, Indiana (S.B. Indiana University 1934, M.D. Indiana University 1936), assistant in anesthesia, Francis Marott Sinex, of Indianapolis, Indiana (A.B. DePauw University 1943, A.M. Indiana University 1944), teaching fellow in biological chemistry, Arthur Kaskel Solomon, of Cambridge (A.B. Princeton University 1934, A.M. Harvard University 1935, Ph.D. Harvard University 1937), assistant professor of physical chemistry, Howard Ingram Suby, of Newton Center (A.B. University of Wisconsin 1930, M.D. Harvard University 1934), assistant in genitourinary surgery, James Joseph Thomas, of Alliance, Ohio (S.B. Mount Union College 1935, M.D. Ohio State University 1940), assistant in anesthesia, Arthur Wallace Tucker, Jr., of Needham (A.B. Dartmouth College 1937, M.D. Harvard University 1941), assistant in obstetrics,

and William Anthony Weiss, of Philadelphia, Pennsylvania (S B Georgetown University 1934, M D Jefferson Medical College 1938), assistant in anesthesia

The College of Physicians of Philadelphia awarded the Alvarenga Prize on July 14, 1946, to Dr William H Feldman, of the Mayo Foundation for Medical Education and Research, in recognition of his studies on chemotherapy in tuberculosis

The Alvarenga Prize was established by the will of Pedro Francisco daCosta Alvarenga, of Lisbon, Portugal, an associate fellow of the College of Physicians, to be awarded annually by the College of Physicians on each anniversary of the death of the testator, July 14, 1883, to the author of a memorial on any branch of and line that is deemed worthy of the prize

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request

Dietotherapy Clinical application of modern nutrition Edited by Michael G Wohl, M D, associate professor of medicine, Temple University School of Medicine, and chairman, Advisory Committee on Nutrition, Philadelphia Department of Public Health. With a foreword by Russell M Wilder, M D, Ph D, professor of medicine and chief of the Department of Medicine, Mayo Foundation, and member of the Committee on Medicine and of the Subcommittee on Medical Nutrition, Division of Medical Sciences, National Research Council. 8°, cloth, 1029 pp, with 93 illustrations. Philadelphia W B Saunders Company, 1945 \$10.00

This new treatise on nutrition in health and disease is a composite work of fifty-eight recognized authorities in various fields of medicine. The objective of the book is to provide the practicing physician and the student of medicine with the sound knowledge of current advances in and practical applications of the rapidly expanding science of nutrition. The subject matter is divided into three parts: normal nutrition, nutrition in periods of physiologic stress and nutrition in disease. Selected lists of references are appended to each chapter.

Preventive Medicine By Mark F Boyd, M D, C P H, field staff member, International Health Division, Rockefeller Foundation. Seventh edition, revised. 8°, cloth, 591 pp, with 187 illustrations and 56 tables. Philadelphia W B Saunders Company, 1945 \$5.50

This standard text has been thoroughly revised and brought up to date. New material has been added, and many divisions have been expanded, rearranged and rewritten. The section dealing with nutrition has been entirely recast in the light of current concepts. Rheumatic fever, leptospirosis and asbestosis are included for the first time. The work is recommended for all medical libraries.

Technical Methods for the Technician By Anson L Brown, M D, director of Dr Brown's Clinical Laboratory and Dr Brown's School for Technicians, Columbus, Ohio. Third edition. 8°, cloth, 707 pp, with 229 illustrations. Columbus, Ohio B B Printing Company, 1944

This standard text written for students and clinical laboratory workers has been thoroughly revised. Many new methods and procedures have been added to the text. The emphasis is on technique, but interpretations are given for most procedures. In this edition new illustrations and colored plates have been added. In the section on serology the author's test for syphilis is presented for the first time. The author concludes his work with a list of one hundred and five standard laboratory reference books. This book should prove valuable to all laboratory workers and serve as a reference source in medical libraries.

Diseases of the Nervous System in Infancy, Childhood and Adolescence By Frank R Ford, M D, associate professor of neurology, Johns Hopkins University. Second edition. 4°, cloth, 1143 pp, with 164 illustrations. Springfield, Illinois Charles C Thomas, 1944 \$12.50

In this second edition of an authoritative text the many errors of the first edition have been corrected and the author has taken advantage of the helpful criticisms offered to him. Select bibliographies are appended to each disease, and the text is amplified by many pertinent case histories. The book is well printed, with a good type, on good paper and is recommended for all medical libraries and to all those interested in the diseases of the nervous system.

Public Medical Care Principles and problems By Franz Goldmann, M D. 8°, cloth, 226 pp. New York Columbia University Press, 1945 \$2.75

In this book Dr Goldmann attempts to give a composite picture of public medical care as a social movement. He deals with community health activities supported by taxation and administered by governmental agencies. In the first part, after a review of the history of public medical care, the author analyzes, interprets and appraises public policy in providing facilities and services for the care of the sick. In the second part he discusses the problem of planning for medical care and shows the potential value of the method of taxation to the development of broad programs of health and social security in the future.

The Autobiography of Science Edited by Forest R Moulton, Ph D, Sc D, and Justus J Schifferes. 8°, cloth, 666 pp. Garden City, New York Doubleday, Doran and Company, Incorporated. \$4.00

The editors of this new history of science have attempted to provide an anthology of the key passages from the master works of all sciences. The selections are in general arranged in chronological order from the time of genesis to modern times. Medicine is well represented in the selections, and this book should be in all historical collections.

Pulmonary Tuberculosis in the Adult Its fundamental aspects By Max Pinner, M D, chief, Division of Pulmonary Diseases, Montefiore Hospital for Chronic Diseases, New York City, and clinical professor of medicine, College of Physicians and Surgeons, Columbia University. 8°, cloth, 579 pp, with 59 illustrations and 3 graphs. Springfield, Illinois Charles C Thomas, 1945 \$7.50

This new work on pulmonary tuberculosis considers the subject in all its phases as interrelated to each other. Extensive bibliographies are appended to each chapter, and each reference is annotated, a new and time-saving feature in bibliographies.

NOTICES

ANNOUNCEMENTS

Dr Marcus W Berman, having returned from military service, announces the opening of his office for the practice of medicine and surgery at 304 Belgrade Avenue, Roshardsle

Dr Sydney Grace, having returned from military service, announces the reopening of his office at 311 Commonwealth Avenue, Boston, for the practice of obstetrics and gynecology

Dr Sidney Olans, having returned from active service with the Army, announces the reopening of his office for the practice of medicine and obstetrics at 20 Intervale Avenue, Medford

Dr Robert H Talkov has returned from military service and will resume the practice of internal medicine with special interest in arthritis and allied rheumatic disease at 375 Commonwealth Avenue, Boston

Number 5

INFECTIOUS HEPATITIS IN MASSACHUSETTS

With a Review of Present Knowledge of the Disease

HARRIET L. HARDY, M.D.,* AND ROY FEEMSTER, M.D.†

BOSTON

THE recent literature describing the experience of the armed forces with infectious hepatitis is voluminous, but reports on the disease in the civilian population have been few. This article summarizes our present knowledge of the disease and indicates how nearly our observations coincide with or differ from those of others. The clinical material used as the basis of this paper has been collected by means of visits to Massachusetts communities from which the disease has been informally reported to the Department of Public Health. Approximately 175 cases of infectious hepatitis were uncovered in Massachusetts in these investigations, but only 151 case histories are used in this report, since in the remaining cases 24 insufficient data were available to make their analysis reliable.

A short explanation of nomenclature in this disease will be useful. "Epidemic catarrhal jaundice" and "nonspirochetal infectious jaundice" are the terms that have been used in the past to designate it. "Infectious hepatic jaundice" appeared as a title in 1937, when it was realized that the infection is localized in the liver rather than in the duodenum and larger bile ducts. At present the term "infectious hepatitis" — or with English authors "infective hepatitis" — is used to designate sporadic cases and "infectious epidemic hepatitis" for groups of cases during outbreaks. An occasional writer refers to infectious hepatitis as "hepatocellular catarrhal icterus";^{2,3} a term of doubtful value.

The limits of this discussion make it impossible to do more than mention the vast store of accumulating facts concerning artificially acquired hepatitis, which is in many ways identical with naturally acquired infectious hepatitis. Oliphant⁴ has shown that the causative organism of infectious hepatitis is present in an infective state in the blood of patients with this disease.

The term "homologous serum jaundice" is used to refer to hepatitis artificially acquired from any cause. The clinical picture produced by this condition is similar to that observed in infectious epidemic hepatitis.⁵⁻⁸ The incubation period is different in the two diseases.⁹⁻¹¹ An attack of homologous serum jaundice does not protect against infectious epidemic hepatitis.^{9,12} It may be that there are separate etiologic agents for the two diseases.

At the present time, artificially acquired hepatitis appearing from a variety of sources is classified as homologous serum jaundice. Reports show that this disease has occurred after the use of certain lots of yellow-fever vaccine,^{5,13-17} measles antiserum,^{18,19} and mumps convalescent serum.^{20,21} Hepatitis after transfusion,^{7,14,19,22} is now a well recognized occurrence. Contamination of syringes by infected serum has been reported both from a diabetic clinic²³ and following the administration of anti-syphilitic arsphenamine.²⁴⁻²⁶

HISTORY

The available medical literature contains many statements concerning jaundice of a contagious variety. Hippocrates knew and wrote of such a disease.²⁷ Letters between Pope Zacharias and St. Boniface in the eighth century A.D.²⁸ describe epidemics of jaundice. The American Civil War produced many cases of a disabling, highly contagious jaundice.²⁹ Pomeroy³⁰ in 1898 in Michigan and Leslie³¹ in 1909 in Maine described outbreaks much like the one to be discussed herein. Cockayne²⁷ in 1912 in England wrote an impressive and complete report of the information and literature then available. His article contains speculation that is now known to be based on facts.

Much was written after the British had had experience with huge numbers of men sick with jaundice at Gallipoli and the Dardanelles in 1915-1916.³²⁻³⁶ From these reports it is apparent that

*Assistant district health officer, Massachusetts Department of Public Health; assistant in medicine, Massachusetts General Hospital.

†Director, Division of Communicable Diseases, Massachusetts Department of Public Health.

Weil's disease was not yet understood Willcox³⁶ in 1919 made a clear classification and separated epidemic catarrhal jaundice from other forms of contagious and noncontagious jaundice³⁷⁻⁴⁷ American observers showed an interest in outbreaks of jaundice, especially Williams,⁴⁸ Wadsworth⁴⁴ and Symmers⁴⁹ in New York State, Hiscock and Rogers⁴⁹ in Connecticut described its occurrence among college students in 1922 Blumer⁵⁰ presented an extensive study of what he called infectious jaundice in the United States in 1923 In that same year, Jones and Minot⁵¹ published a careful clinical estimate of the disease, pleading for more attention to its extent and potential dangers The English literature of the 1930's⁵²⁻⁵⁹ contains scattered reports of outbreaks, as does the literature of other countries,⁶⁰⁻⁷⁰ with a few American records^{71, 72}

One cannot be certain that all these outbreaks belonged in a single group, since the etiologic agent had not been discovered, but there does appear to be a basic pattern in the histories of such episodes Since the outbreak of hostilities in the Mediterranean theater, the German,⁷³⁻⁷⁵ Italian,⁷⁶ French,⁷⁷ British⁷⁸⁻⁸⁰ and American armies,^{81, 82} as well as refugees in Palestine,⁸³⁻⁸⁵ have suffered serious morbidity from infectious hepatitis The Navy has by no means escaped⁸⁶⁻⁸⁸

ETIOLOGIC AGENT

It is now held that infectious hepatitis is caused by a specific virus This virus has not yet been grown in the laboratory Swedish investigators⁸⁹ in 1938 believed that they had successfully infected swine with the causative agent of infectious hepatitis This has not been confirmed German authors^{90, 91} claimed to have been able to make the organism grow in the chorioallantoic membrane of chicks Other German workers⁹² claimed that the organism could be passed to birds This work is not convincing and has not been repeated Cameron⁹³ and Van Rooyen and Gordon⁹⁴ tried without success to infect animals during their experience in the Middle East Hovle⁹⁵ in England tried every possible route in mice, guinea pigs and chick embryos but was equally unsuccessful Paul and his group¹² have tried all the animals named, as well as monkeys, but have not been able to produce infectious hepatitis in any of them

It has been possible to transmit infectious hepatitis to human volunteers This has been done in England¹⁰ and America¹² It is now known that human volunteers can develop the disease following the parenteral injection of small amounts of infective serum,^{4, 9} following ingestion of infective serum or feces¹⁰ and following the spraying of infective feces into the nasopharyngeal passages¹² Certain facts about the virus itself are also known Havens⁹⁶ has shown it to be extremely resistant to heat and capable of passing through the finest filters MacCallum and Bradley¹⁰ have demonstrated that the

organism remains actively infective after drying and after storage in the dried state up to fourteen months Stokes et al⁹⁷ have suggested that chlorination of water contaminated with the virus of infectious hepatitis attenuates but does not kill the organism The virus may prove to be resistant to chemicals in the strengths in which they are ordinarily used for the purification of water

EPIDEMIOLOGY

Age

Reports lead one to believe that infectious hepatitis, like other contagious diseases, may attack persons of any age^{46, 50, 55-57, 85, 98-100} The age distribution of the 151 cases collected in Massachusetts was as follows under five years, 8.6 per cent, five to nine, 17.2 per cent, ten to fourteen, 17.9 per cent, fifteen to nineteen, 11.9 per cent, twenty to twenty-four, 6.7 per cent, twenty-five to twenty-nine, 9.3 per cent, thirty to thirty-four, 11.2 per cent, thirty-five to thirty-nine, 9.3 per cent, and over forty, 8.0 per cent Persons between six and forty years of age are oftenest affected The authors reporting on special age groups, such as college students^{49, 101} and soldiers,^{75, 80, 102-104} do not, of course, have a wide range, but health officers in England^{55, 105} and physicians in rural communities in America^{31, 50, 106} show a wider distribution of ages affected Our observations in Massachusetts in 1945 suggest that different age groups are preponderantly affected in different communities within a single outbreak period Community A in Massachusetts, for instance, showed a higher rate among young adults, although the population was not preponderantly of any particular age group, whereas Community C showed a far greater incidence among the children of early school age (six to ten years), in spite of the fact that adolescents and young adults were heavily exposed at school and in the home Chance or the operation of unknown laws of susceptibility must account for this variation

Sex

The disease affects both sexes practically equally In our series, there were 71 males and 80 females

Geographical Distribution

There is no question that infectious hepatitis has a world-wide distribution For the reader's interest, references to a number of epidemics believed to belong under the heading of epidemic infectious hepatitis are cited^{27, 28, 32, 35, 37, 42, 43, 47, 50-53, 55-70, 76, 77, 107}

Incidence

According to the records, the incidence of infectious hepatitis has varied enormously A workable concept is that this disease, like poliomyelitis, is always present in the form of sporadic cases Epidemics take place from time to time and in various regions when natural conditions favor the growth of the virus and when artificial conditions of crowding

and poor conditions of all sorts exist. In 1898, Pomeroy³⁰ reported 676 cases among 30,000 persons in Michigan. Williams⁴⁸ reports 700 cases in the 1921 outbreak in New York State and considers this to be about 50 per cent of the known cases. Pickles⁵² describes 250 cases in 5700 persons exposed. Rogers¹⁰¹ states that the average number of cases at Yale University in a nonepidemic year is 22, and in an epidemic year he reports 63 cases within fifteen days.

Stowman¹⁰⁸ refers to infectious hepatitis as the "new disease" of World War II, without giving supportive evidence of its newness. The disease is reportable in the Scandinavian countries, Finland and Switzerland, these countries reported 65,000 cases in 1943. Army experience^{80, 82, 109} is cited to give an idea of the extensiveness of the disease at present. The Navy⁸⁶⁻⁸⁸ in the South Pacific reports infectious hepatitis, as have the German,^{73, 75} Italian⁷⁶ and French⁷⁷ armies. Since the disease is reportable in only a few states in this country, we have no idea of its incidence. Blumer¹¹⁰ writes that it is reportable in California and that 118 cases were reported in 1943 and 335 in 1944. Handy¹⁰⁶ encountered well over 100 cases in a small New Hampshire community of 2500 persons between October, 1944, and April, 1945. Between May and July, 1945, we encountered reports of 175 cases in Massachusetts.

Season

In this small series, patients had onsets in every month, the lowest number being 9 in August and December and the highest, 80 in April^{25, 30, 50-55, 70, 75, 78, 85, 101-103, 111}

Immunity

Only speculation is possible concerning immunity following infectious hepatitis until a means is developed of determining whether a subject is having or has had the disease. The fact that the gamma globulin of blood pools apparently contains antibodies against infectious hepatitis¹¹² is suggestive of permanent immunity after an attack. Furthermore, the age group attacked—six to forty years—suggests that older persons have acquired immunity by a previous attack. A physician who has been in practice in the same community for over forty years recalls a series of cases that he attended thirty-one years ago that were identical in every way with those existing in 1945 in the same community. In only 1 case in our series was there a second attack. A woman teacher of forty-two years sick with the disease in 1945 gave a clear history of having had a similar clinical picture at sixteen years of age after exposure during an epidemic of so-called "yellow jaundice" in her schoolroom.

Period of Infectivity

Because of the epidemic possibilities of infectious hepatitis, it is important to know the period

of infectivity. Bates⁵⁹ considered the period to be four weeks after the onset of jaundice, and Pickles⁵² estimated it as eight days before and up to two weeks after onset. Pickles remarked that the period of infectivity must be short, because of his observation that new cases came at regular thirty-day intervals. It is now known from transmission experiments that blood serum and feces are infectious during the active stages of the disease.⁴³ More evidence on this point is accumulating.

Incubation Period

Transmission experiments prove that under controlled conditions the incubation period of infectious hepatitis is about thirty days.^{10, 12} Reports of epidemics suggest that many factors determine the time between cases in uncontrolled environments. Cockayne²⁷ and Glover⁵⁶ put the period between cases as four days, Pickles⁵² puts it at thirty-five days. Rogers¹⁰¹ states that the period of incubation for his cases was three to nineteen days, with an average of seven. Cameron⁸³ estimates the time as one to six months.

In our observation in Massachusetts in 1945, the period between cases in a household varied so widely that there scarcely seemed to be a pattern. In one family, 3 children became ill within six days at two-day intervals, in another family there were eight days, fourteen days, twenty-two days and twenty-eight days between the 4 cases. In two families living in adjoining homes, there were 3 cases in one house and 2 in another, and between each case there was a two-month interval, except in the last case, in which there was a twenty-one-day interval after probable exposure. The shorter periods apparently represent infection from the same source with variation in dates of onset, the longer ones may represent incubation periods of secondary cases. Because the virus is hardy⁹⁶ and may survive in the environment as well as in the body of the patient or carrier, it is often difficult to trace the source of infection and thereby determine the day of exposure. It is our impression that many factors influence the rapidity with which the virus produces symptoms. Such factors are undoubtedly responsible for some of the variation in the length of the incubation period. Stokes's⁹⁷ work with chemical alteration of the virus leads one to speculate that the incubation period may be lengthened by unknown factors affecting the virulence of the causative organism.

Method of Transmission

The important question of the method of transmission has not yet been settled. Although it is difficult to trace cases to contact with other known cases, the fact that cases occur in groups points to person-to-person contact as a method of spread. In our own series, contact of patients with probably infected groups was recorded in 139 cases, leaving only 12 sporadic cases in which no such association

Weil's disease was not yet understood Willcox³⁸ in 1919 made a clear classification and separated epidemic catarrhal jaundice from other forms of contagious and noncontagious jaundice³⁷⁻⁴⁷ American observers showed an interest in outbreaks of jaundice, especially Williams,⁴⁸ Wadsworth⁴⁴ and Symmers⁴⁰ in New York State, Hiscock and Rogers⁴⁶ in Connecticut described its occurrence among college students in 1922 Blumer⁵⁰ presented an extensive study of what he called infectious jaundice in the United States in 1923 In that same year, Jones and Minot⁵¹ published a careful clinical estimate of the disease, pleading for more attention to its extent and potential dangers The English literature of the 1930's⁵²⁻⁵⁹ contains scattered reports of outbreaks, as does the literature of other countries,⁶⁰⁻⁷⁰ with a few American records^{71, 72}

One cannot be certain that all these outbreaks belonged in a single group, since the etiologic agent had not been discovered, but there does appear to be a basic pattern in the histories of such episodes Since the outbreak of hostilities in the Mediterranean theater, the German,⁷³⁻⁷⁵ Italian,⁷⁶ French,⁷⁷ British⁷⁸⁻⁸⁰ and American armies,^{81, 82} as well as refugees in Palestine,⁸³⁻⁸⁵ have suffered serious morbidity from infectious hepatitis The Navy has by no means escaped⁸⁶⁻⁸⁸

Geographical Distribution

There is no question that infectious hepatitis has a world-wide distribution For the reader's interest, references to a number of epidemics believed to belong under the heading of epidemic infectious hepatitis are cited^{27, 28, 32, 35, 37, 42, 43, 47, 50-53, 55-70, 75, 77, 107}

Incidence

According to the records, the incidence of infectious hepatitis has varied enormously A workable concept is that this disease, like poliomyelitis, is always present in the form of sporadic cases Epidemics take place from time to time and in various regions when natural conditions favor the growth of the virus and when artificial conditions of crowding

further show that the excreta from such volunteer patients and from patients in the preicteric phase of infectious hepatitis will, if fed to susceptible persons, cause the disease, so that it seems more than likely that nonicteric cases exist, as observers have insisted. Their presence would help to explain the spread of the disease when it has not been possible to show contact. In view of their probable existence, it may not be necessary to postulate healthy carriers. Physicians whom we consulted commented on the unusual incidence of nonspecific vomiting and diarrhea in their experience during the past months, and one report¹¹⁸ is suggestive. Housewives spontaneously reported the same occurrence in their homes and those of their neighbors coincident with infectious hepatitis. There may well be some relation that will become clear when the behavior of the virus of this disease is understood.

PATHOLOGY

Infectious hepatitis, or catarrhal jaundice as the disease was named until recently in this country, has been held to be an inflammatory process causing edema in the large bile ducts and the duodenum, thus accounting for jaundice and other evidence of obstruction to the normal excretion of bile pigment.¹¹⁹ Cockayne²⁷ in 1912 pointed accurately to the relation between the disease and acute yellow atrophy. He suggested that a weakened liver made it simpler for the virus to attack that organ. In the years following this, the concept of catarrhal inflammation held sway. Throughout, some observers held the liver to be the site of disease. Jones and Minot¹²⁰ in 1923 brought out clinical evidence that pointed to the liver as the site of infection. Blumer,⁵⁰ also in 1923, reported a pathologist's finding in Buffalo, New York, to the effect that in 1921 there was more acute yellow atrophy than he had ever seen in one year. There was simultaneously a widespread outbreak of epidemic jaundice, as it was called. Experimental work by Humsforth and Glynn¹²¹ is relevant to the present concept of the pathologic physiology of infectious hepatitis.

Knowledge of the pathologic process has recently become more certain.¹²²⁻¹²⁴ The needle biopsy^{125, 126} has been introduced and in time, according to reports, will prove a reasonable diagnostic procedure for widespread use. Dible¹²⁷ has reported, after considerable experience, that most cases are pathologically benign and that following recovery no changes in the liver cells are visible. A small group of his patients showed mild but definite residual zonal fibrosis. Another small group showed classic cirrhosis as an end result. The fatal cases show acute and subacute hepatic necrosis of all grades of severity. The present view is that the virus causes damage in the hepatic cells themselves and that the clinical picture of obstruction depends on the inability of the cells to handle the bile pigment.

Lucké¹²⁸ has presented in detail the autopsy findings in 125 fatal cases of probable infectious hepatitis. These cases occurred among men in the armed forces. The livers in all cases showed parenchymal cell damage of all degrees, ending in acute yellow atrophy. In 75 per cent of the cases the spleen showed hyperplastic changes. Some of the kidneys showed cholemic nephrosis. In a moderate number of cases, there was edema of the brain and a meningo-encephalitis. Lucké mentions phlegmon of the intestinal tract. Lesions in the gastric mucosa of patients moderately ill with infectious hepatitis have been seen with the gastroscope.¹²³ Lucké's presentation suggests that infectious hepatitis may cause widespread damage in the body.

CLINICAL CHARACTERISTICS

This report on infectious hepatitis is based on histories obtained from hospitals and physicians, supplemented by talks with the patients themselves. Of the 151 patients, 22 were cared for in the hospital and 129 in their homes. These cases have been classified as 117 undeniable cases of infectious hepatitis and 34 likely cases. The former patients presented a history of contact, a convincing clinical picture and jaundice, whereas the latter gave a history of contact and a medical history characteristic of infectious hepatitis but no visible jaundice. All these patients came from communities in which the disease existed in sufficient numbers to give acceptable epidemiologic ground for considering the presence of infectious hepatitis to be epidemic in character.

Character of Onset

The onsets presented varying pictures in length and character. There were 31 cases of grippelike onset and 52 cases of abrupt or gradual onset, presenting chiefly gastrointestinal symptoms. Seventeen patients complained bitterly of abdominal pain at the onset; 5 of these localized their pains specifically in the right lower quadrant of the abdomen, and in 3 of these cases appendectomy was performed, 10 patients complained of severe headache, and 7 of some backache at the onset. Twenty-two mothers spoke of apathy, listlessness and drowsiness on the part of their children at this stage. A striking feature was that the onsets varied from community to community, suggesting that the strain of the virus may vary from one location to another. In Community A, the onsets were largely gastrointestinal in character, in Community B and Community D, grippelike onsets with inflamed throats led physicians to think of disease of the respiratory tract. In Community C, we encountered histories of headache, sleepiness and apathy as characteristic of the onset. A diagnosis of poliomyelitis, a not unknown occurrence,^{129, 130} was considered in 1 case.

The length of onset varied from a few days in 46 cases to two weeks in 16 cases and four weeks and

could be found. The kind of contact is shown in Table 1.

Blumer⁵⁰ made a similar classification.

From Table 2 it does not appear that a "clean" home is a guarantee that infectious hepatitis will not gain a foothold. It will be noted, however, that there is a preponderance of single cases in these homes. The same observation was made in regard

TABLE 1 *Nature of Contact*

PLACE	FAMILY CONTACT	SCHOOL CONTACT	JOB CONTACT	MISCELLANEOUS GROUP CONTACTS (PARTY MEETING)
Community A	33	8	15	6
Community B	4	11	0	1

Community D	6	7	1	1
Totals	56	40	18	9

to communities. Community A was suburban and prosperous, the homes were well kept, and the persons involved were for the most part conscious of sound health practice. Communities B and D were rural and less economically favored, the homes were less well cared for, and considerable ignorance and opposition to such public-health measures as milk pasteurization were encountered. Community C

TABLE 2 *Number of Cases Occurring in "Dirty" and "Clean" Homes*

fell between, with a portion of both groups described. From Table 1 it appears that infectious hepatitis is independent of anything but the presence of the virus in the community, together with probable likely contact in the majority of cases, and individual susceptibility, since obviously not all those exposed in the six-to-forty-year group became ill.

Some of the possible methods of transmission discussed in the literature should be noted.

Insects. Two observers^{75, 104} thought that flies were important. Another writer¹⁰³ suggested bedbugs. The presence of infectious hepatitis at all seasons seems proof that except in rare instances of extremely bad sanitation insects are unimportant.

Fomites. There are no data that either prove or disprove the importance of contaminated articles. Since the virus is resistant to heat and chemicals,⁹⁸ infectious hepatitis may be transmitted by fomites.

Suggestive circumstances are found in the fact that 2 of the patients with infectious hepatitis in our series were postmen who handled letters coming from a theater of war known to be heavily infected with the disease. We learned also of a woman with infectious hepatitis who in previous months had received daily letters from her son, who was sick in Italy with the disease.

Water. There are three reports dealing with water as the vehicle for the virus of infectious hepatitis. Fraser⁵⁴ in Canada believed that his epidemiologic observations, together with proved fecal contamination of the water supply, showed an epidemic of infectious hepatitis to have been water-borne. Hallgren^{113, 114} in Sweden worked out a similar theory when an explosive outbreak appeared in an institution and a nearby village, both of which used water from the same contaminated reservoir. Neefe and Stokes¹¹⁵ claim that an outbreak in a girls' camp was due to contamination of a well by the feces of a patient with infectious hepatitis introduced into the camp early in the season. They produced sickness simulating infectious hepatitis in one of a group of volunteers by feeding them water from the supposedly contaminated well in the camp.¹¹⁶ Water seemed unimportant in our study, since there were multiple sources of drinking water, none of them convincingly contaminated. Cockayne⁹⁷ believed that water was ruled out by the evidence of infectious hepatitis in troops who were forbidden water and were given only tea to drink, yet among whom cases continued to appear.

Food. Rogers⁴⁹ and Blumer⁵⁰ thought that food might be the vehicle for the causative agent of infectious hepatitis. It appears certain that food-borne outbreaks have occurred in the past, because transmission experiments with volunteers have shown that the feces of active cases contain the virus of infectious hepatitis.¹²

Air. This has been the favorite explanation over the years.^{27, 30, 55, 58, 59, 100, 116, 117} From early concepts of bad air and vapors to the concept of droplet infection through talking, coughing and sneezing, most observers urged this theory even before the presence of a specific virus was demonstrated. In our study, droplet infection has seemed an important method of transmission because of contact between cases without the sharing of food or water.

In summary, study of the literature and observation of 151 cases of infectious hepatitis in Massachusetts in 1944-1945 led us to conclude that the disease is probably transmitted in more than one way — by droplet infection, by contaminated food and perhaps by water.

The possibility that nonicteric patients are potential carriers is still unexplored. Until a definite way of making a diagnosis has been developed, the existence of such cases can only be a subject of speculation. Work with volunteers shows that there are undoubtedly nonicteric cases.^{10, 12} These studies

further show that the excreta from such volunteer patients and from patients in the preicteric phase of infectious hepatitis will, if fed to susceptible persons, cause the disease, so that it seems more than likely that nonicteric cases exist, as observers have insisted. Their presence would help to explain the spread of the disease when it has not been possible to show contact. In view of their probable existence, it may not be necessary to postulate healthy carriers. Physicians whom we consulted commented on the unusual incidence of nonspecific vomiting and diarrhea in their experience during the past months, and one report¹¹⁸ is suggestive. Housewives spontaneously reported the same occurrence in their homes and those of their neighbors coincident with infectious hepatitis. There may well be some relation that will become clear when the behavior of the virus of this disease is understood.

PATHOLOGY

Infectious hepatitis, or catarrhal jaundice as the disease was named until recently in this country, has been held to be an inflammatory process causing edema in the large bile ducts and the duodenum, thus accounting for jaundice and other evidence of obstruction to the normal excretion of bile pigment.¹¹⁹ Cockayne²⁷ in 1912 pointed accurately to the relation between the disease and acute yellow atrophy. He suggested that a weakened liver made it simpler for the virus to attack that organ. In the years following this, the concept of catarrhal inflammation held sway. Throughout, some observers held the liver to be the site of disease. Jones and Minot¹²⁰ in 1923 brought out clinical evidence that pointed to the liver as the site of infection. Blumer,⁵⁰ also in 1923, reported a pathologist's finding in Buffalo, New York, to the effect that in 1921 there was more acute yellow atrophy than he had ever seen in one year. There was simultaneously a widespread outbreak of epidemic jaundice, as it was called. Experimental work by Himsworth and Glynn¹²¹ is relevant to the present concept of the pathologic physiology of infectious hepatitis.

Knowledge of the pathologic process has recently become more certain.¹²²⁻¹²⁴ The needle biopsy^{125, 126} has been introduced and in time, according to reports, will prove a reasonable diagnostic procedure for widespread use. Dible¹²⁷ has reported, after considerable experience, that most cases are pathologically benign and that following recovery no changes in the liver cells are visible. A small group of his patients showed mild but definite residual zonal fibrosis. Another small group showed classic cirrhosis as an end result. The fatal cases show acute and subacute hepatic necrosis of all grades of severity. The present view is that the virus causes damage in the hepatic cells themselves and that the clinical picture of obstruction depends on the inability of the cells to handle the bile pigment.

Lucké¹²² has presented in detail the autopsy findings in 125 fatal cases of probable infectious hepatitis. These cases occurred among men in the armed forces. The livers in all cases showed parenchymal cell damage of all degrees, ending in acute yellow atrophy. In 75 per cent of the cases the spleen showed hyperplastic changes. Some of the kidneys showed cholemic nephrosis. In a moderate number of cases, there was edema of the brain and a meningo-encephalitis. Lucké mentions phlegmon of the intestinal tract. Lesions in the gastric mucosa of patients moderately ill with infectious hepatitis have been seen with the gastroscope.¹²⁸ Lucké's presentation suggests that infectious hepatitis may cause widespread damage in the body.

CLINICAL CHARACTERISTICS

This report on infectious hepatitis is based on histories obtained from hospitals and physicians, supplemented by talks with the patients themselves. Of the 151 patients, 22 were cared for in the hospital and 129 in their homes. These cases have been classified as 117 undeniable cases of infectious hepatitis and 34 likely cases. The former patients presented a history of contact, a convincing clinical picture and jaundice, whereas the latter gave a history of contact and a medical history characteristic of infectious hepatitis but no visible jaundice. All these patients came from communities in which the disease existed in sufficient numbers to give acceptable epidemiologic ground for considering the presence of infectious hepatitis to be epidemic in character.

Character of Onset

The onsets presented varying pictures in length and character. There were 31 cases of grippelike onset and 52 cases of abrupt or gradual onset, presenting chiefly gastrointestinal symptoms. Seventeen patients complained bitterly of abdominal pain at the onset, 5 of these localized their pains specifically in the right lower quadrant of the abdomen, and in 3 of these cases appendectomy was performed, 10 patients complained of severe headache, and 7 of some backache at the onset. Twenty-two mothers spoke of apathy, listlessness and drowsiness on the part of their children at this stage. A striking feature was that the onsets varied from community to community, suggesting that the strain of the virus may vary from one location to another. In Community A, the onsets were largely gastrointestinal in character, in Community B and Community D, grippelike onsets with inflamed throats led physicians to think of disease of the respiratory tract. In Community C, we encountered histories of headache, sleepiness and apathy as characteristic of the onset. A diagnosis of poliomyelitis, a not unknown occurrence,^{129, 130} was considered in 1 case.

The length of onset varied from a few days in 46 cases to two weeks in 16 cases and four weeks and

over in 4 cases Handy¹⁰⁶ had a similar experience in 1945 in New Hampshire. He reported caring for patients who felt ill and had vague gastrointestinal complaints for two months, suggesting the possibility of peptic ulcer. We have collected similar histories. Eventually such patients developed the usual picture of infectious hepatitis. These observations go far toward explaining the reports of widely varying incubation periods. With long, vague onset periods, depending to a degree on the subjective reaction of the patient, and with many patients ill with infectious hepatitis who never seek medical advice, the incubation period and period of onset cannot be definitely described during an outbreak in general medical practice.

Precipitating Factors

Factors apparently operating to precipitate infectious hepatitis were striking. These may account for the apparent susceptibility of one or two persons exposed to the same degree as the other members within a family or the other pupils in a school-room. There are reports of dysentery,^{33, 36, 111, 121-123} paratyphoid fever,³² chilling,^{31, 36, 102} respiratory infection^{27, 48, 55, 59, 101} and alcoholic excesses^{35, 80} as antecedent and important factors in outbreaks of infectious hepatitis in institutions and troops.

There were 44 cases of precipitating factors in this series. These included 10 cases of previous recent bacterial infection, 8 of a moderately large intake of alcohol, 15 of fatigue attendant on war work, 4 of pregnancy, 5 of recent moderate or large doses of sulfadiazine and 2 of striking dietary deficiency in children. It is relevant that in a family of several children the child who acquired infectious hepatitis was the one who had had chronic middle-ear disease or was recovering from one of the exanthemas. Another interesting observation was that in three homes in which only the father was sick he had been on night duty as well as daytime duty.

Character and Duration of Jaundice

The usual first sign of approaching jaundice is the appearance of bile in the urine. Thirty patients reported this symptom. The next step in most cases is a noticeable yellow tint in the scleras. The process may cease at this point, especially in children. We observed four families in which a parent had an easily recognized case of infectious hepatitis and a child, after a febrile onset, had only discoloration of the scleras for a few days. If the process is of sufficient severity, jaundice of the skin becomes evident and may last from two days to a matter of weeks, the average being two weeks. The duration of jaundice in this series is shown in Table 3. When the jaundice disappears, it goes in the inverse order, bile appearing in the urine transiently in the convalescent period. If the jaundice persists for over three weeks, some other diagnosis than infectious hepatitis must be considered. When other diagnoses

are ruled out, it is reasonable to consider that irreversible changes in the liver may be taking place¹¹⁴ and that in a few cases these will end in fatal acute yellow atrophy.

Allied Symptoms and Signs

For clarity, the allied symptoms and signs encountered in infectious hepatitis are listed in Table 4 in order of frequency of appearance. In general, the subjective complaints begin to disappear with the

TABLE 3 Duration of Jaundice

DURATION	No. of Cases
Less than 1 week	10
One week	31
Two weeks	29
Three weeks	16
Four weeks	5
More than 4 weeks	4

appearance of jaundice. This does not hold true in the severer cases. It should also be emphasized that many patients are encountered in an epidemic group who have virtually no symptoms except mild jaundice. We saw cases in family outbreaks so mild that no physician had been consulted.

Some of these symptoms and signs are interesting enough to deserve separate comment. Sore breasts and menstrual irregularities may be due to disturbances in steroid excretion by the liver as a result of hepatic-cell dysfunction.¹²⁴ Edema can probably always be demonstrated at some stage in a case of infectious hepatitis. Lucké's¹²⁵ report brought out

TABLE 4 Symptoms and Signs Other Than Those Associated with Jaundice

the frequency of ascites and edema of the brain in fatal cases. Cockayne²⁷ in 1912 reported diuresis as defervescence of the disease begins. Williams¹²⁶ has commented on this in his observation on hospitalized cases of infectious hepatitis. In the 32 cases with involvement of the central nervous sys-

tem, the symptoms include irritability, apathy, drowsiness, stiff neck, temporary delirium and depression. These, with the 10 cases of headache, constitute an appreciable group of the 151 cases of infectious hepatitis. The literature reveals that other observers^{31, 129, 130} have encountered such symptoms. Lucké¹²² suggests that the loss of detoxifying power of the liver may well account for these frequently encountered symptoms. The occurrence of a rash has been previously reported,^{31, 80} as have cases of urticaria^{28, 136}. No explanation has been offered. With the well known occurrence of herpes labialis and a concomitant infection, it is surprising that only 1 case was encountered. We know of no reason why pruritus was so infrequent.

Severity

We were struck, as others^{23, 30, 70, 106, 138} have been, with the increase in severity of infectious hepatitis with age. This was not without exception, since 3 men kept at their jobs with no apparent immediate ill effect during ten days of jaundice, whereas 2 children were ill for five weeks and complained of vomiting and epigastric pain long after clinical jaundice had subsided.

Pregnant women were especially ill, as others^{50, 70, 85, 137} have noted. When one bears in mind the relation between infectious hepatitis and acute yellow atrophy and considers the fetus as an extra load for the liver, this observation is understandable. In our series there were 4 pregnant women. Two were delivered four to six weeks before the expected date. One of these women had a violent onset of infectious hepatitis, which the attending physician properly considered a toxemia of pregnancy. The diagnosis of infectious hepatitis was established on clear epidemiologic grounds. One woman aborted in the tenth week of pregnancy. One woman in her third month did not abort but had a violent and prolonged attack of infectious hepatitis, which she acquired from her daughter.

Alcohol may play a part in increasing the severity of an attack of infectious hepatitis. Damodaran and Hartfall⁸⁰ thought that this might well be the case. Observations made of protein-starved livers of famine victims in India suggest that dietary deficiency may, if severe enough, predispose to a serious attack of infectious hepatitis.¹²¹ Drugs and industrial poisons, known to be specific liver toxins, should prove important in altering the course of infectious hepatitis.

Nonicteric Cases

Liver-function tests on volunteers¹² given infectious material show that there are undoubtedly persons who demonstrate evidence of hepatic disease without developing clinically recognizable infectious hepatitis. We have included 34 such patients in this series. The onset of their disease may be identical with that of typical infectious

hepatitis. Usually bile can be demonstrated in the urine, but this occurs at times in many infections. These patients may have symptoms of gastrointestinal distress, marked anorexia and weight loss, but they never develop visible jaundice.

Physical Signs

A characteristic physical sign besides jaundice is enlargement and tenderness of the liver edge.^{28, 51, 70, 120, 125, 129} We encountered such a finding in 10 cases. The pulse is not characteristically slowed.⁵⁰ The spleen is enlarged in 5 to 40 per cent of cases.^{59, 70, 83, 138} Lucké¹²² noted enlargement of the spleen in 75 per cent of his fatal cases. Barker et al.⁸² report lymph-node enlargement, a finding that we never encountered. If the disease progresses to definite jaundice in a given case, the stools become clay-colored, as in obstructive jaundice from any cause. Edema may be present.

Laboratory Findings

Physicians caring for cases in our study used the foam test to demonstrate biliruria early in the disease. Twenty-six positive reports of biliruria were noted by them. Barker et al.⁸² have used the methylene-blue test. Albuminuria is occasionally found, perhaps simply as part of an acute febrile illness, it was encountered in 7 cases in this series. Lucké¹²² reports renal changes in fatal cases that he considers due to a cholemic nephrosis. Another report¹⁴⁰ notes cases of nephrosis in an epidemic of infectious hepatitis.

Hospitalized cases that can be carefully followed show a rise in bile pigment in the blood as the disease progresses. The level of bilirubinemia is the best index of the severity of a given case of infectious hepatitis. Liver-function tests, used in a wide variety, show changes that vary considerably.^{82, 138, 141-144} These tests are not definitely useful, since they do not parallel the clinical status of the patient. An increase in prothrombin time, especially with a poor response to vitamin K therapy, is indicative of a bad prognosis. In our series, no evidence of hemorrhagic tendency was noted. In reports of epidemics, hemorrhagic events have been noted in severe cases.^{40, 70, 80, 82, 138} Lucké¹²² reported that 109 of his 125 fatal cases showed some evidence of hemorrhage.

The white-cell count is of some value in diagnosis at the onset, when it may rise to 10,000 to 12,000. As the disease progresses, the count falls to a normal level of 8000 and occasionally to 4000. There is a relative lymphocytosis throughout the illness. Jones⁵¹ has discussed this, and Barker, Capps and Allen⁸² recently presented their findings, as have earlier observers.^{35, 58} The sedimentation time is not helpful.^{145, 146}

Differential Diagnosis

During the onset, a diagnosis is difficult, since a specific test is lacking. Acute disease of the upper

respiratory tract, grippe, influenza, an atypical pneumonia, enteric infection such as dysentery, acute appendicitis^{28, 35, 59, 117} and infectious mononucleosis come to mind. In the presence of an epidemic series of cases of infectious hepatitis, however, the problem is relatively simple. The white-cell count during onset is helpful, especially in ruling out acute appendicitis. It is elevated to levels around 20,000 in Weil's disease, which usually presents a more serious clinical picture from the start, and the specific organism *Leptospira icterohaemorrhagiae* can be found in the blood.

Infectious mononucleosis may produce jaundice.¹⁴⁷ If done at the right time, heterophile agglutination with sheep's cells will decide this point. In the tropics, malaria and sandfly fever have to be differentiated.

Sequelae

The convalescent period varies with the severity of the given case, together with the age and temperament of the patient. In young adults, we obtained uniform histories of weakness, fatigability and loss of energy as characterizing convalescence. This period ranged from two weeks to four months, with the average about one month. This time of disability was a serious problem for the armed forces both in naturally acquired infectious hepatitis⁸² and in hepatitis occurring after the giving of yellow-fever vaccine⁸ and blood transfusion.⁷

Return of the appetite was often slow. In the absence of laboratory aid, this symptom is of distinct help in estimating the return of liver function to normal. Mothers remarked of their convalescent children — and 6 adult patients agreed — that when the appetite did return it was practically impossible to give the patient enough to eat.

Weight loss was a striking feature of infectious hepatitis, as others^{82, 106} have noted. In the 47 cases in which a sufficiently reliable history was obtained, there was a weight loss of five to ten pounds in 20 cases, of ten to twenty pounds in 24 cases and of thirty pounds in 3 cases.

Relapses took place in 4 cases, with a return of jaundice in 2 of them and a prolonged period of bilirubin in 2. Returning to work too soon was the explanation in all these cases. Barker, Capps and Allen⁸² have done considerable work on this point. It is an important one for civilian physicians to consider, with diminished liver function in mind as a sequela. Altschule,¹²⁹ Kornberg¹⁴¹ and Rennie¹⁴⁴ have done careful laboratory work with patients who have recovered from infectious hepatitis and in normal controls. Their results suggest that a certain number of patients emerge from an attack of infectious hepatitis with some impairment of liver function. This work also suggests the significant fact that the impairment may not parallel the clinical course of the attack. Caravati¹⁴⁵ describes the so-called "post-hepatitis syndrome."

Prognosis

The mortality figures of different epidemics have been carefully reviewed by Lucké,¹²² who gives the range as 0.24 to 0.44 per cent. Stowman,¹⁰⁸ in his recent report of present-day infectious hepatitis, reports the death rate as ranging from 0.1 to 1.0 per cent. In the present series there was 1 death. This occurred in one of a small series of cases in an institution after three days of clinical illness, during the last twenty-four hours of which the patient was in a coma. Autopsy showed complete hepatic necrosis. Cockayne²⁷ reported such cases.

TREATMENT

General Management

Dietary management has been the standard weapon in the care of infectious hepatitis. Dible et al.¹²⁷ report histologic evidence of damage and isolation of hepatic cells from their columns in the early phase of infectious hepatitis, following which the cells can be shown to be without glycogen. Jones¹⁴⁹ considers a high sugar intake extremely important as protection for the hepatic cells. Certainly in severe cases, nausea and vomiting are dramatically relieved by intravenous dextrose in concentrations of 5 to 25 per cent. Observations made in the present series show that a high intake of sugar by mouth was the most satisfactory measure subjectively, a daily intake of 300-400 gm of carbohydrate being a reasonable goal. It is best given by mouth whenever possible.

Barker, Capps and Allen⁸² think that a high protein intake is important and quote György's¹⁵⁰ work. British workers^{151, 152} are not satisfied that high protein feeding alters the course of the disease. Handling of proteins is one of the liver's foremost and most complicated tasks, and it may be best not to give the liver large doses of protein to handle while it is disabled.

Barker, Capps and Allen remark that the matter of low fat intake is not yet settled. Experience shows that, except in the most benign cases of infectious hepatitis, the gastrointestinal tract cannot easily handle fat. Bile is being excreted with difficulty and in some cases not at all, so that fat digestion is impaired.

Vitamin K need only be added in the event of an attack of infectious hepatitis sufficiently severe to change the prothrombin level. In this series, the only evidence of unusual bleeding was a history of flooding during the menstrual flow, which was coincidental with the period of jaundice of 3 women having infectious hepatitis.

Jones¹⁴⁹ stresses the use of adequate doses of the vitamin B complex during the acute and early convalescent phases of infectious hepatitis, because the liver is temporarily unable to act in the synthesis of this vitamin. Barker, Capps and Allen,⁸² on the basis of György's experimental work, believe that too much vitamin B may be harmful.

We should like to point out that the widespread use of sulfonamide compounds at the onset of all acute infections may be injudicious in the event that the case proves to be one of infectious hepatitis. The liver acts as a detoxifying agent in handling these drugs. If, as transmission experiments with volunteer subjects suggest, the liver function is impaired before the onset of clinical symptoms,¹² use of the sulfonamides is certainly contraindicated. Perhaps these drugs can act as a precipitating factor. To illustrate this point, reference may be made to a family in which 5 of the 12 children had infectious hepatitis. The mother called one physician for 3 of the sick children and another physician for the other 2. The former were treated with a mild cathartic, a high intake of sugar and bed rest, with prompt recovery. The latter, given large doses of a sulfonamide in the onset period, had to be hospitalized and had jaundice of longer duration than did any other patients of the same age group in this series. This observation is certainly suggestive that the sulfonamide drugs should not be administered in infectious hepatitis.

Morphine and the barbiturates should be used cautiously in severe infectious hepatitis, because of the presence of active liver disease. Calomel and violent purges are only mentioned to be dismissed, as belonging to the days when infectious hepatitis was thought to be an ascending cholangitis and duodenitis, with swelling around the ampulla of Vater.¹¹⁹

Prophylactic Treatment

A new chapter in the management of infectious hepatitis is opening with the use of gamma globulin, the antibody fraction of plasma employed in the attenuation of measles. It is of no proved value therapeutically.¹²⁰ Stokes and Neefe¹²⁴ believed that they had used it successfully in the summer of 1944 to halt the progress of an epidemic of infectious hepatitis in a girls' camp. Recent reports by Gellis et al.¹²² suggest that gamma globulin confers passive immunity against infectious hepatitis for at least six to eight weeks. Prevention is desirable for pregnant women, as has been indicated. Modification will be sought as in measles because of evidence that one attack confers immunity, with few exceptions. We gave modifying doses—0.25 cc per pound of body weight—to the members of two families in Community A who were heavily exposed to infectious hepatitis by immediate family contact. Three of these subjects had episodes eight weeks later, suggesting that they were having modified infectious hepatitis. In one family in which 3 persons were given gamma globulin, a baby of nineteen months had a slight fever, was peevish, refused to eat and had light-colored stools for three days, whereas two other small children in the family, recently recovered from infectious hepatitis, were not sick at the time.

Supplies of gamma globulin will become available to Massachusetts physicians if further study confirms its usefulness in prevention and modification. American plasma has been used in controlling epidemic infectious hepatitis in the Mediterranean theater.¹¹²

SUMMARY

Infectious hepatitis occurs sporadically and in epidemic form over a wide geographical area. It seems certain that the disease is caused by a specific virus with an apparent affinity for the liver. The disease in most cases confers lifelong immunity.

The transmission of infectious hepatitis, on the basis of present knowledge, takes place by contact of a susceptible person either with a patient having the disease or with material contaminated by the causative virus. It seems certain that the virus can be carried in food. It may be carried in water.

The findings in 151 cases of infectious hepatitis in Massachusetts occurring during 1944–1945 are presented and discussed.

A plea is entered for the recognition and careful handling of infectious hepatitis. This disease clearly may cause irreversible liver changes. Our observations lead us to believe it is a serious disease in pregnant women.

Gamma globulin has no place in the treatment of the active phase of infectious hepatitis. It has been shown to be capable of producing passive immunity of six to eight weeks' duration and should be useful in the control of small outbreaks. Further study may prove that gamma globulin given during the incubation period can modify infectious hepatitis, in a manner similar to its action in measles.

An attempt has been made to include all references to epidemics of jaundice that, in the light of present knowledge, may be designated as infectious (epidemic) hepatitis. References to foreign articles, not read and not available, are included for their interest in showing the incidence and wide geographical distribution of this disease.

MODERN GOVERNMENTAL MEDICAL PROBLEMS*

BRIGADIER GENERAL R W BLISS, M C, USA†

MY brief remarks will be made from the viewpoint of one who has spent his life in the Army Medical Corps. This viewpoint, however narrow, has been broadened by the experience of two wars and the intimate association in them with mobilized civilian medicine and, between wars, a more limited association with my civilian colleagues. This country has just been through not only the biggest war in its history but also the biggest medical operation in the history of the world. I believe that everyone can profit by reviewing this experience. My comments will be limited to a review of a few crucial aspects of the Army's medical service. I shall touch on the medical problems confronting the Government as a whole and suggest one or two points of contact between the Government and civilian medical practice.

First, as to the Army, few realize that the total number of patients in all Army hospitals in 1938, both in the United States and overseas, totaled less than 10,000, which represented* during this war the patient load at a single large Army medical center. With troops in the prewar period widely dispersed and with a total of only 10,000 patients, it was clearly impossible for the Army to develop a high degree of medical specialization. We did the best we could by evacuating patients who required specialized treatment to general hospitals. This made it possible for the Army to keep some personnel at a high pitch of skill by affording them the quantity and variety of clinical material that is essential for the practice of specialized medicine.

During the war approximately 15,000,000 patients were admitted to some twelve hundred Army hospitals. For two years, between 1943 and 1945, the number of patients in hospitals was never below 270,000, and there was a peak load in April, 1945, of 544,000. At the start of the war the Army Medical Corps was slightly in excess of 1000 doctors. This number was expanded until some 47,000 were on duty. Despite the availability of these doctors, we were severely pressed for specialists and in many crucial areas simply did not have enough to go around — this in spite of the most careful supervision to see that every doctor was placed where his ability could be utilized to the fullest. As an example of this supervisory endeavor, when the hospitals in this country were busiest, a careful study by Brigadier General Fred W Rankin showed that every board member in the surgical specialties was actually practicing in his specialty or acting as a consultant in the Office of the Surgeon General or in

one of the geographical-area service commands. This scarcity of trained specialists made it necessary to organize all the general hospitals in approximately twenty specialty centers, such as those devoted to neurosurgery, ophthalmologic surgery, amputations, thoracic surgery, psychiatry, plastic surgery and tropical medicine, and to concentrate our key personnel at them. Patients requiring specialized care went to these centers, where qualified staffs were available. The success of this intricate system depended on a highly efficient medical regulating mechanism for distributing patients speedily and correctly. As many as 57,000 patients returned from overseas within a single month. Each patient was sent to the general or convalescent hospital suitable for his treatment and nearest his home.

Despite this concentration of specialists and patients, the shortages in skilled personnel were sufficiently marked to force the Army to engage in an extensive training program. Outstanding in this respect was the training of neuropsychiatrists, the Army more than doubled the numbers from civilian life. Since tropical medicine was an esoteric field, the Army had to train almost 100 per cent of the doctors used in this division. Large numbers of younger men were given training courses in anesthesia and radiology, as well as in other branches of medicine.

In this system of specialized medicine the supervision of patients and the assignment of personnel were largely the responsibility of our consultants. These men were chosen carefully and given a great amount of authority. There were consultants not only in the office of the Surgeon General but on the staffs of each major force. I regret to say that almost without exception these men who served so well during the war have now returned to civilian life. We have all realized the large contribution that they made and the benefits that were derived from their work. The high achievements and the outstanding professional advancements made during the war were dependent to a marked degree on the development and operation of this consultant system. We realize that a small postwar Army cannot possibly justify the full-time assignment of a large number of key specialists. We have, therefore, taken steps to develop a consultant system that will utilize civilian experts on a part-time basis.

You may also be interested in our plans for professional training. After the last war, our numbers were too small to permit more than a few men to continue with their studies outside Army facilities. This time we are seeking to provide adequate numbers so that a considerable part of the Medical Corps can at all times be away at school or otherwise pursuing postgraduate training. In passing, it is

*An address given at the Boston Sectional Meeting of the American College of Surgeons, Boston, March 19, 1946.

of interest that the Surgeon General has recommended and the General Staff has approved financial incentives for men who have been passed by their specialty boards

The Army's situation can be summarized in the following terms. We developed during the war a highly specialized type of medicine, which was the principal reason that we were able to furnish such excellent medical care to the sick and wounded. We are doing our utmost to perpetuate this system in peace.

Now a word concerning the medical service of the federal government as a whole. The various governmental agencies have been largely independent in thought and action, but there has always been some integration among the medical services of the Government. In prewar days the Army provided medical care for a considerable number of patients of the Veterans Administration and was also responsible for the medical care of members of the Civilian Conservation Corps.

During the war the medical services of the Army and the Navy went their own way, except in theaters of operations. There it was made evident that some integration of available means was definitely necessary. To a limited extent, Army and Navy hospitalization and evacuation operations were combined, with mutual satisfaction and effectiveness in parts of some theaters. At present, both the Army and the Navy are doing what they can to assist the Veterans Administration, which has an acute shortage of beds and personnel. For instance, the Army is holding all patients with tuberculosis who would ordinarily be discharged from the service to the Veterans Administration. We have made approximately 10,000 beds available in Army hospitals for the care of veterans.

I have studied the problem of the possibility or desirability of integrating, in whole or in part, the federal hospitals. Boston with its environs is typical of many large areas in this country. Here there are Army, Navy, Veterans Administration and Public Health Service hospitals — each operating independently. Here also there are state, county and city hospitals and large civilian teaching institutions. If we are to make the best use of our limited governmental resources, in fact of our limited national resources, it seems appropriate — at least to me — that the activities of these separate systems be somehow co-ordinated,

correlated or integrated into governmental medical centers for the care of patients entitled by law to governmental medical aid. Perhaps we should establish specialty centers, transfer patients accordingly and assign our specialists not in terms of the service to which they belong but to the hospital designated for their specialty at the same time utilizing to the full the staffs and facilities of the civilian teaching institutions. This should result in better treatment of patients. A combination of these independent facilities with their physical means and their co-ordinated staffs would provide an educational nucleus for the successful training of interns, residents, nurses and technicians for governmental service and should add to the attractiveness of a governmental medical career. As an integral part of such a medical center, there would be a central diagnostic and treatment clinic through which all except emergency patients would funnel and where the all-important outpatient treatment could be concentrated.

A significant finding in this brief study is the marked discrepancy between the available and required numbers of specialized personnel. There is no prospect whatever, so far as I can see, for the four federal agencies, operating independently, to meet their full responsibilities for hospitalization through the employment of full-time staffs. If these responsibilities are to be met, — and I am sure that each of us believes that they must be met, — the old barriers between governmental and civilian medicine must be broken down. As you know, the medical director of the Veterans Administration is seeking the assistance of medical schools and of the civilian medical profession to the greatest possible degree. The Army is looking forward to seeking the assistance of civilian consultants on a part-time basis. In short, the period of complete isolation and self-sufficiency appears to be ending.

The Army, the federal government and in fact American medicine at large face a host of serious medical problems. A preliminary review of governmental medical requirements and means indicates that we shall be hard pressed, at best, if we are to advance as rapidly as we should. Surely there is no room for the inefficiencies of isolation. The successful solution of a problem involves not only good will but intensive study. The good will of all of us exists in the attempt to solve the problems confronting governmental medicine. I believe that intensive study is needed.

ACUTE POLIOMYELITIS IN PREGNANCY*

Its Occurrence according to the Month of Pregnancy and Sex of Fetus

W LLOYD AYCOCK, M D †

BOSTON

A CLINICAL impression that poliomyelitis occurs with undue frequency during pregnancy and its possible importance in relation to susceptibility have been emphasized in previous papers¹⁻⁴. There are many reports of cases in the literature that deal with various aspects of the disease in the pregnant mother, such as effects of the disease on the mother and the fetus or obstetric problems created by the occurrence of the disease. Few reports have dealt specifically with the question of frequency of the disease in pregnancy or its significance. Within the age groups concerned pregnancy is relatively frequent and poliomyelitis is infrequent. For this reason it is difficult to establish any association between the two conditions on the basis of frequency alone. Comparisons of the percentage of cases that occur in pregnant women with the estimated percentage of women of correspond-

available on pregnancy were known to be incomplete. For one of them, the District of Columbia, the number of expected cases in pregnancy based on birth rates for the registration area — probably too high a figure for Washington — was 18. Of the 18 cases in women of twenty to forty-five years of age, 4 (22 per cent) occurred during pregnancy. In Duluth, Minnesota, there were 8 cases in adult women and 1 of these patients was pregnant, the expectancy was 0.8 per cent. Fox and Sennett⁵ report that of 6 women with poliomyelitis admitted to South View Hospital, Milwaukee, 4 were pregnant. These authors also review earlier reports such as that of Brahdy and Lenarsky, which showed that of 15 admitted women over the age of nineteen, 3 (20 per cent) were pregnant.

Waaler⁶ has recently reported that of 23 women over eighteen years of age who had poliomyelitis in

Totals	54		3.767	40	3.102	10

ing ages who are pregnant at any given time, as calculated from birth rates, have indicated an increased occurrence of the disease during pregnancy. In an outbreak in Detroit in 1939, in which the expected chance occurrence was 0.95, 4 cases were observed in pregnant women. Eleven of the paralyzed women were over the age of twenty, and in 3 of these cases (27 per cent) paralysis developed during pregnancy.⁴ This is the first study in which a record concerning pregnancy was obtained in all cases of the disease. In data obtained through the co-operation of health departments of sixty-three cities or counties in fifteen states, including Massachusetts, and in the District of Columbia, with an expected occurrence of 58 cases in 1944, 73 cases were listed. In all but two of these areas the data

1941, in an outbreak at Bergen, Norway, 7 (30 per cent) were pregnant, as compared with an estimated pregnancy rate for women in the same age group in the same locality of 6.4 per cent.

Through the co-operation of the Division of Communicable Diseases of the Massachusetts Department of Public Health, it has been ascertained that 10 of the 54 women between fifteen and forty-five years of age with poliomyelitis in 1945 were pregnant (Table 1). Actually, the question of pregnancy was verified in only 40 of these cases.

All these studies relating to the frequency of poliomyelitis concern numbers of cases too small to be convincing in themselves. In this respect the study of the question presents a problem similar to that in poliomyelitis following tonsillectomy. The relation of tonsillectomy to poliomyelitis became evident not on the basis of the actual frequency of its occurrence but from the localized occurrence of

*From the Department of Preventive Medicine and Epidemiology, Harvard Medical School and Harvard School of Public Health.
†Associate professor of preventive medicine and hygiene, Harvard Medical School and Harvard School of Public Health.

a particular type of the disease (bulbar poliomyelitis) at a specific interval following tonsillectomy.^{7, 8} Similar evidence of localization is seen in data collected over a period of years from various sources on cases of poliomyelitis in pregnancy.

In my records there are 236 cases in which the month of pregnancy in which the disease occurred is known, and 9 cases in which it occurred from two to twenty-three days after delivery, which is within the range of the incubation period of the disease. There is no indication of a tendency of the disease to occur at any specific period of pregnancy. There are fewer cases in the first two months of pregnancy, but this is to be interpreted as a probable dis-

and 15 women with female infants and only 4 with male infants in the third (Fig 1). There were 3 cases that occurred post partum, — five, five and twenty-three days, respectively, — suggesting that infection was initiated during pregnancy.

Confirmation of this indicated localization of poliomyelitis in the first trimester in pregnancies with a male fetus, with a shift in the last trimester to a predominance in pregnancies with a female fetus, would establish a causal relation between pregnancy and poliomyelitis. In addition, it would afford a basis for the elucidation of physiologic or endocrine factors at different stages of pregnancy, that are involved in poliomyelitis. Furthermore, such a biphasic phenomenon may be a reflection of physiologic factors in pregnancy with a male or female fetus, a conjoint study with which might afford a clearer understanding of both susceptibility to poliomyelitis and factors related to sex ratio in pregnancy.

SUMMARY

Available statistics suggest that pregnancy predisposes to acute poliomyelitis and that there is a tendency for the disease to occur in the first trimester in women who are carrying a male fetus and in the third trimester in those who are carrying a female fetus.

It is hoped that additional data relative to these matters will be made available in the near future.

crepancy in the data. I myself have missed a case in early pregnancy in a nurse in a Boston hospital, whom I thought to be unmarried. Of 42 of these cases in which both the month of pregnancy when the disease occurred and the sex of the child are known, there were 8 women with male infants and 1 woman with a female infant in the first trimester, equal numbers of infants of both sexes in the second

CLINICAL NOTE

AN UNUSUAL CASE OF A FOREIGN BODY
IN THE NECK*

RICHARD H. MILLER, M.D.†

BOSTON

THIS report, which is extremely brief, is made chiefly because it presents an extraordinary traumatic episode. There is one lesson to be drawn from it that no member of this society needs to have told him.

A few years ago, in June, a group of children were playing on the wide and high piazza surrounding their house. Suddenly a boy of six lost his balance and tumbled head foremost from the piazza into a thick mass of rosebushes. He could not get up and moaned with pain, and his head was twisted at such an unusual angle that some of the others thought that his neck was broken. He was carried into the

trating wound. When the platysma muscle was severed, the rough, jagged end of a rose stalk protruded into the wound. A firm grip was obtained on it by means of a clamp, and gentle traction was started. There was an immediate massive hemorrhage from below, apparently of venous blood. The moment this happened the stalk was jammed back, and the bleeding at once ceased. The incision was carried almost to the upper border of the clavicle. When the contents of the carotid sheath had been dissected out, the stalk was found to penetrate completely the internal jugular vein and to extend behind the common carotid artery into the thoracic cavity. The jugular vein was carefully freed and tied with No. 1 chromic catgut above and below the point of penetration of the stalk. Before further traction on the stalk was attempted, the common carotid artery was dissected out as low down as possible and a double strand of No. 2 chromic catgut was placed around it, so that it could be pulled up quickly and tied. The stalk was then pulled up gently and there was no further bleeding. The patient was given 1500 units of tetanus antitoxin.

The patient's postoperative condition was excellent, and convalescence was without any untoward event.

When the stalk (Fig. 1) was laid on the boy's chest and neck, it extended from the wound of entrance down into the right thoracic cavity until the sharp end lay just behind the 4th rib.

It may seem to take a great stretch of the imagination to see how one can draw a direct and definite analogy between a surgeon's removing a

FIGURE 1 Actual Tracing of the Stalk

The total length was 19.7 cm, with an average thickness of 0.8 cm. The blunt end of the stalk, seen at the right, was palpable just behind the angle of the jaw. The sharp end of the stalk penetrated the skin behind the angle of the jaw and went cleanly through the internal jugular vein, going down inside the thoracic cavity and stopping at the level of the fourth rib anteriorly.

house, where the family physician saw him. The patient was sent to the local hospital, where I examined him. The rest of the case report follows.

Physical examination revealed a rugged boy lying on his back with his head sharply flexed to the left, a position from which it could not be moved. At the angle of the right jaw was a jagged, penetrating wound 2 cm long, and lateral to it, under the skin and platysma muscle, could be felt the upper end of a thick, rodlike foreign body, which seemed to extend a long distance downward in the neck, if not into the thorax. The rest of the examination was negative. There was no significant evidence of shock.

It was at once decided that the penetrating object was probably a long stick and that an immediate attempt should be made to remove it.

Under ether anesthesia, a short, vertical incision was made over the most prominent part of the bulge, behind the pene-

foreign body of this sort from a child's neck and a collision at sea between two large vessels, but there is a direct one. It concerns the pushing of the rose stalk back into the neck and thorax. On September 18, 1914, the Canadian Pacific Steamship *Empress of Ireland* sank in the Saint Lawrence River with the loss of 1024 lives, having been rammed amidships by a Danish collier. The captain of the collier immediately reversed his engines and pulled his ship out, leaving the *Empress of Ireland* with a gaping hole, which made her sink almost immediately, if he had given the order "Full speed ahead," the vessels would have jammed together and the *Empress of Ireland* would probably have stayed afloat for some time.

264 Beacon Street

MEDICAL PROGRESS

DISEASES OF THE VEINS

JOHN HOMANS, M D *

BOSTON

IN A previous review,¹ evidence by pathologists for the origin of venous thrombosis below the knees was presented. Serious illnesses, especially cardiac, injuries, operations and childbirth were proved to be the usual background for thrombosis, much of which was terminal and unnoticed clinically. The state of the blood platelets following childbirth and surgical operations was shown to predispose toward thrombosis, and patients might be more or less liable to it, as indicated by their tolerance for or sensitivity to heparin. Local conditions in the lower limbs, however, appeared to be more important factors than any others. Early ambulation did not by any means overcome such influences.

Pulmonary embolism, it was stated, was to be expected chiefly in patients over fifty years of age, but might occur in younger persons, even in those acquiring thrombosis in everyday life. It often imitated cardiac and pulmonary disease.

The distinction between an early, quiet, thrombosis (phlebothrombosis) and a late, obstructive thrombosis (thrombophlebitis) was brought out, as well as the various courses that any one lower-leg thrombosis might pursue, and the importance of this distinction was shown to lie in the necessity of applying the appropriate treatment to the different stages — vein interruptions being most appropriate for the early stage as a prevention of embolism.

Diagnosis of venous thrombosis was believed to depend not only on various local signs in the lower leg but also on an elevation of pulse rate and temperature as written on the clinical chart. Pulmonary embolism was shown to call attention to thrombosis oftener than any other single sign. The importance of electrocardiography in making the diagnosis was noted. Phlebography appeared to be regarded as a trustworthy diagnostic aid by some but not by others. Treatment of thromboembolic disease by anticoagulants and by surgical interruption of veins was discussed. The anticoagulants were gaining favor, particularly in the prevention of postoperative thrombosis, and most reports were devoted to this aspect of the subject. Little information was at hand regarding how long the treatment should be continued and how the break-off should be managed. Attempts to make the administration of heparin less expensive and more convenient than by the continuous intravenous method

were described, these including the use of a menstruum from which slow absorption could take place.

Surgical treatment appeared to have become more or less standardized, division of the femoral vein being most frequently used, but a tendency was evident to perform some higher ligations, including that of the vena cava, to cope with high, advancing processes and obscure peripheral sources of embolism. In any event, bilateral disease was always to be considered. Suction of soft thrombus from the common femoral vein appeared necessary in many cases, but it was considered not altogether satisfactory and the question of combining anticoagulants with surgery was raised.

Finally, some notes were made on the frequency with which venous thrombosis might be associated with arterial embolisms and thromboses in the limbs, a tendency that might account for some pulmonary embolism in connection with amputation for arterial deficiency.

RECENT CONTRIBUTIONS TO THE THROMBOEMBOLIC PROBLEM

Subsequent contributions to the thromboembolic problem amplify and expand previous observations, without adding anything of a revolutionary nature.

Etiology

Hunter and his associates,² continuing their earlier studies, compare a second series with their first. They undertook to determine at autopsy the incidence of thrombosis in the femoral and adductor veins of the thigh and to learn, if possible, the effect of exercise on thrombus formation. Regarding recumbency as the greatest single factor in thrombus formation, and believing that phlebothrombosis might occur within two days after recumbency had been started, they found that in patients exercised systematically until shortly before death (from any cause), only 18 per cent exhibited thrombosis at autopsy, as opposed to 53 per cent when exercise was not employed. In respect to local, mechanical factors in the legs themselves, these authors quote from Simpson's³ comment that pulmonary embolism was strikingly increased in elderly persons cared for in London bomb-proof shelters who reclined in deck chairs or something similar, the wooden crossbar causing pressure on the veins on the back of the leg and popliteal space.

*Surgeon emeritus Peter Bent Brigham Hospital

They believe that in hospitals all attendants should be embolism-conscious, particularly in respect to the lower legs as a source

Hyperprothrombinemia, as a threat of thrombosis and embolism, is further discussed by Shapiro.⁴ Observations were made on 59 cases in which present or recent thromboembolization was observed. Making use of a particular method of prothrombin estimation, Shapiro found that reactive hyperprothrombinemia could be detected by serial estimations after surgical operations, childbirth, acute coronary occlusion and some other disorders in a large proportion of cases. The detection of such a state could be used not only as an indication for treatment but also in the differential diagnosis between pulmonary infarction and other lesions presenting a similar symptomatology.

Venous pressures during various surgical operations have been studied by Davis, Gilman and Freedberg,⁵ with the thought in mind that venospasm may play a part in the observed elevated pressures found.

That such vasoconstrictions and elevated pressures may lead to postoperative venous thrombosis is suggested but of course not proved.

Clinical Course

There is an evident tendency to belittle the distinction between phlebothrombosis and thrombophlebitis, except as they represent stages of the disorder. For example, Fine and Starr⁶ encountered a soft detachable thrombus proximal to what seemed to be a typical thrombophlebitis. They declare that when embolism occurs in the presence of phlegmasia alba dolens it need not have come from the quiet, opposite leg but from the obstructed side. Thus, they recommend explorations, at an early or even an advanced stage of the acute swelling. This supports Allen, Linton and Donaldson's⁷ view that in its early progress an obstructive thrombophlebitis is a proper subject for surgery. On the other hand, Ochsner,⁸ in a complete discussion of intravenous clotting, holds the distinction between the stages to have clinical importance, not only because phlebothrombosis should be treated surgically but also because the various sorts of vascular spasm caused by thrombophlebitis, some of which may actually be contralateral, are most effectively treated by lumbar sympathetic block. Such matters will be reconsidered below under the heading "Treatment." They are mentioned here to show that the stages of the thrombosing process in the veins of the lower limbs are worthy of attention, and that if one concentrates so heavily on the embolic side of thrombosis as to ignore the distinction between the stages, one may fail to have in mind the serious reflex vascular constrictions, some of which have permanent disabling effects.

Diagnosis

Stress is laid on the value of early diagnosis, both by phlebography and physical signs. The value of the former is in controversy. Bauer¹ makes it a routine practice and pays great attention to the technic. He always cuts down on and cannulates the terminal trunk of the lesser saphenous vein below the external malleolus, declaring that its immediate deep connections, especially with the fibular (peroneal) veins, where much thrombosis originates, make it the ideal spot for the introduction of the contrast medium. Diodrast, or an equivalent iodine preparation, is used, and exposure to the x-ray from above the knee to the ankle is made with the limb in the horizontal position. This technic is believed to be decidedly more accurate than the insertion of a needle into any available superficial vein—diversion of the flow into the deep veins being forced by a rubber constriction about the upper calf—and probably accounts for Bauer's reliance on phlebography. Anderson and Patterson,¹⁰ however, make use of the needle-and-tourniquet method and depend on phlebography to determine the type of treatment to be used in cases of chronic or recurrent venous thrombosis. They regard it as unnecessary as a preliminary to ligation in cases of acute or recurrent venous thrombosis when definite local clinical signs are present. Apparently Ochsner,¹¹ who once strongly favored phlebography, now relies on it much less than formerly.

Other refinements in early diagnosis are offered by Moses,¹² who explores the posterior calf for deep tenderness by firm pressure with the fingertips and follows the discovery of a tender spot by lateral pressure between the fingers and palm, and by Tyson and Goodlet,¹³ who find that elevated venous pressure in the veins of the foot or ankle offers better evidence of thrombosis in the calf than can be secured by phlebography. Most observers look on slight enlargement, local deep tenderness and minor increases in the tone and irritability of the calf muscles, as ascertained by daily routine examinations, as most important. Spontaneous pain and pain on forced dorsiflexion of the foot are relatively late signs.

On the whole, little has been added lately to the diagnostic armamentarium, but if phlebography is to be used, the vein behind the external malleolus had better be exposed and cannulated. Consistent practice of this method in skilled hands will probably produce better results than any other one observation, the situation and extent of the process usually being revealed to the expert.

Pulmonary Embolism

The recent literature on pulmonary embolism adds a little to the understanding of both the path-

ologic physiology and the diagnosis. Attempts to study it experimentally have been made. Kinney, Haynes and Dexter¹⁴ have introduced a venous catheter into the pulmonary artery in the dog by way of the jugular vein and right heart. So far, only the method has been described, but from an informal communication, as yet unpublished, I learn that occlusion of a large pulmonary artery, by the inflation of a balloon at the tip of the catheter, produces no change in the pulse rate or respiratory rate, the systemic blood pressure, the right ventricular pressure or the electrocardiogram. Only when infarction follows do signs and symptoms appear. If, however, emboli (Lycopodium spores) are introduced into a lobe, acute symptoms, including a fall of blood pressure, dyspnea, elevated right ventricular pressure and acute electrocardiographic changes, at once occur. Apparently this reaction is due to a generalized constriction of the pulmonary arteriolar bed, that is, it is not confined to the affected lobe. Dexter and his associates are interested in the attempt to correlate these findings in human beings, and their observations should prove valuable.

Statistically, the thromboembolic problem is still being dealt with chiefly from the postoperative and post-traumatic viewpoint, although many of those most familiar with the subject evidently hesitate to rely on figures, even those secured from large clinics. Thus, Allen, Linton and Donaldson⁷ comment that venous thrombosis is commoner in certain clinics and certain geographic locations than in others and that the age of the patient is of utmost importance in the consideration of the danger of fatal embolism in thromboembolic disease. They are so impressed with the increased danger from pulmonary embolism in the aged that they have begun to employ prophylactic vein ligation in prostatic patients, cancer subjects and even some cardiac patients of the older age groups. They find little danger of fatal embolism in patients under forty years of age.

As a result of a large experience in a Swedish hospital, Bauer and Jorpes¹⁵ state that unless prophylactic and therapeutic measures are used to prevent it, thrombosis develops in 1 of every 60 patients who undergo operations or who receive other forms of treatment in surgical or medical wards, and 1 in every 5 or 6 patients who suffer thrombosis dies of pulmonary embolism. My comment is that the incidence of thrombosis given by these authors is extraordinarily low and their percentage of fatal embolisms rather high.

I consider that present-day statistics on both thrombosis and embolism merely emphasize the significance of the problem and that a study of the early signs of pulmonary embolism, together with an understanding of its nature and course, is of the greatest importance, both in medicine and in surgery.

The mode of production of pulmonary embolism has been interestingly discussed by Chapman and Linton¹⁶. Hitherto, they write, the emphasis on sudden death in the act of defecation, parturition, coition or lifting and straining at work or sports has been placed on changes in venous pressure and total hemodynamics due primarily to the heart itself. They explain so-called "bedpan" and similar deaths as due to a preliminary rise of venous pressure and blood volume in the lower limbs, by which the insecurely thrombosed veins are suddenly distended and pieces of thrombus are broken off, as pressure falls and the veins are emptied toward the heart, the embolus is washed along with the accumulated blood. Doubtless this explanation is true, but it should not be forgotten that patients suffering oppressive epigastric discomfort in the early stages of embolism may try for a bowel movement as a means of relief.

Pulmonary embolism from obscure sources is reported by Hampton, Prandoni and King¹⁷. Ten cases were observed, all of which were ambulatory and gave no history of phlebitis. The correct diagnosis was made only after considerable study. Dyspnea and chest pain were usually important clues. Probable sources of emboli were found in leg veins, pelvic veins, thrombosed hemorrhoidal veins and the plexus associated with the prostate. Anticoagulant therapy was successfully employed.

Surgical Treatment

The controversy between the advocates of ligation and of anticoagulants concerns not only the definitive treatment of thrombosis in the leg veins but also prophylaxis. I should preface the presentation of the two points of view by saying that all grant the value of maintaining muscular tone, exercising the legs and keeping up circulatory efficiency in patients forced into life in bed and by acknowledging that the advocates of early ambulation make no claim for the radical lessening of postoperative thrombosis by this means, some rather low figures (Blodgett and Beattie¹⁸) even suggesting that thrombosis is thereby increased.

The anticoagulants are represented by heparin and dicumarol and ligation mainly by bilateral ligation or section of the femoral vein, with the occasional employment of interruption of the iliac vein or vena cava.

I present first the operative surgical standpoint, which is represented most emphatically by Allen, Linton and Donaldson⁷. They believe in routine bilateral interruption of the femoral vein in the groin in all cases of thrombosis whether or not embolism has occurred, and in cases of early thrombophlebitis of the obstructive sort. Regarding the latter stage of the disease, they think that thrombectomy relieves the patient of many of the late complications that are well known to result from thrombophlebitis. They are begin-

ning to use bilateral section of the femoral vein in cardiac patients if an infarction has occurred or there are signs of thrombosis in the legs, but they have also made some prophylactic sections before any definite threat of embolism has presented itself. They have employed prophylactic ligation of the femoral vein in a small group of patients with fractures of the hip and in a good many prostatic patients. They believe that there is a definite future for prophylactic vein division, although they are not fully satisfied concerning the indications.

As regards the level of vein interruption, these authors like the idea of opening the superficial femoral vein distal to the profunda, although they make no special point of the exact level to be used. Their statistics, however, show that they have ligated the superficial femoral vein far oftener than the common vein, — in fact, in proportion of about four to one.

Fine and Starr⁶ are equally surgically minded. They are strongly in favor of bilateral ligation and prefer the common femoral level for vein interruption, believing that any resulting edema is of minor consequence compared with the greater safety of section proximal to the profunda branches. They are opposed to any distinction between early thrombosis and thrombophlebitis, for they think that embolism can occur in the presence of the latter, and they differ somewhat from Allen, Linton and Donaldson in making little distinction between the early and late stages of the obstructive, inflammatory disease. They speak favorably of ligations higher than the inguinal ligament as having less serious aftereffects than does ligation of the common femoral vein and say that such interruptions — of the common iliac vein or vena cava — seem to add no danger and result in fewer postoperative complications.

Veal and Hussey¹⁰ throw an interesting light on the level of vein interruption in a series of 84 cases, in 39 of which embolism had preceded ligation. In the latter group 9 patients suffered further embolism after ligation. Of these 9 cases, embolism was believed to have occurred from the opposite or untreated side in 5, but in the other 4 the source of the embolus was the femoral vein above the point ligated. Veal and Hussey argue from these figures that surgery failed because of inadequate surgical treatment rather than because the principle of the treatment was faulty. In the other 45 cases, in which ligation was performed before the development of pulmonary embolism, there were no cases of embolism following the operation. My own experience supports Veal and Hussey's contention. Satisfactory as is ligation below (distal to) the profunda in many early cases, unexpected tragic embolisms have occurred from a point proximal to the interruption.

There are occasional reports of other disasters following vein ligation. Dennis²⁰ operated on a fifty-nine-year-old man for a rather acute, late

thrombosis following a hernia operation. There had been considerable pain, pinkness and engorgement of the leg. The saphenous vein was thrombosed and palpable. The femoral vein was divided at the saphenofemoral junction and was found to be only incompletely obstructed. As a result of ligation of the vein, the leg at once became deeply engorged and distended with blood. Sympathetic blocks gave no relief. There was a good deal of shock, and the systolic blood pressure fell to 40. The administration of plasma brought no improvement. The leg was cold, tense and bluish-black. The deep fascia (aponeurosis) was divided from below the knee into the upper thigh on both sides of the leg, and the femoral artery was found to be pulsating normally. This operation relieved the violent, acute venous congestion, and both the leg and the patient's life were saved at the expense of considerable disability to the leg itself. My comment on this episode is that I have seen 2 cases of similar sort. In both, a large blood clot formed in the depth of the calf, both required extensive opening on the aponeurosis, and in both cases the clot became infected. Neither leg, however, was lost. Evidently, when the collateral vessels are already widely occupied by thrombus, interruption of the common femoral vein, as yet only partly obstructed, may trap an enormous amount of venous blood in the leg, resulting in both local and general circulatory damage — even shock.

Little is said by anyone about the obstinate edemas that occur following division of the common femoral vein, although Fine and Starr⁶ allude to them and Allen, Linton and Donaldson⁷ assert that they need not seriously be considered. It is my own belief that extremely careful supervision of the convalescence, with gradual resumption of exercise in the erect position, first without weight-bearing and later with it, especially if each course of exercises is balanced by a period of elevation of the legs in bed, will obviate most of the undesirable after-effects. This is especially true in the unusual and perhaps unexpected cases of serious venous obstruction following ligation of the common femoral vein.

Ochsner,⁸ whom I have already quoted as emphasizing the distinction between the various stages of thrombosis, believes in operations for phlebothrombosis, making use of lumbar sympathetic blocks for what he distinguishes as the inflammatory obstructive type causing reflex vasospasm.

De Takats and Fowler²¹ reserve ligation of the femoral vein for such patients as have suffered a pulmonary infarction and show evidence of thrombosis in the calf. For these, they recommend ligation distal to the profunda. They regard ligation of the common femoral vein as a cause of chronic edema in some cases. They are, however, greatly interested in the use of heparin and dicumarol and, as has already been stated, make a point of studying the

reaction of the coagulation time to a test dose of heparin, believing that the patient's so-called "heparin tolerance" is of real clinical importance. Their discussion of the use of anticoagulants will be considered later under that heading.

The higher vein interruptions — that is, those above the common femoral vein — are of a good deal of interest. I²² myself have advocated ligation or actual section of the common iliac vein for definitely unilateral processes — such, for instance, as occur in everyday life following minor trauma — and also for recurrent unilateral thrombosis. Interruption of the common iliac vein offers a vastly better collateral circulation than is available when the common femoral vein is ligated, especially in cases of fairly widespread thrombosis in the thigh without complete obstruction of the femoral vein itself. The difficulty with such operations is that in many chronic or recurrent processes both common iliac veins may be very friable and easily injured, that the left, for anatomical reasons, is often inaccessible and that a general anesthetic is required, as opposed to the local infiltration so satisfactory in the case of the femoral vein. It will be noted, however, that Fine and Starr⁶ regard these operations as adding no appreciable risk. Bancroft²³ reports a satisfactory experience with them in a study of 12 cases in which sixteen thrombectomies were performed for thrombosis discovered at the operative level, but notes 1 death from embolism. All his operations were iliac explorations, and three were bilateral. He gave heparin by Loewe's method (see below) following operation and regards high vein sections as being on the whole safe and life-saving. Satisfactory as many operations on the common iliac vein have proved to be, they do not cover the problem of bilateral thrombosis, since separate incisions are required for the two sides and this seems a decidedly overcomplicated procedure when ligation of the vena cava can be performed at one stroke at only a little higher level.

Divisions of the vena cava have been employed in many cases when a bilateral process is present and appears to be uncontrollable or when the source of serious embolism is so obscure that one authoritative step to stop it must be taken. O'Neil²⁴ has had a highly satisfactory experience with these operations, regards them as exceedingly useful, has run into little danger in performing them and finds little disability afterward. He reports a considerable series of cases. A favorable account of ligation of the vena cava, with a history of the procedure, is offered by Northway and Buxton.²⁵ Still another report comes from Gaston and Folsom,²⁶ and Kern and Berman²⁷ record a successful division of the vena cava for a septic thrombosing process. It is unnecessary to emphasize that the approach to the vena cava offers difficulties not inherent in operations at a lower level. It is easy to reach the great vein through a lateral retroperitoneal incision, but the field offered by the unilateral exposure is so limited that if some of the delicate

lateral veins entering the vena cava are torn, as by even the gentle pressure of a blunt ligature-carrier, it is extremely difficult to control the bleeding. Linton, in a personal communication, states that the best approach is by a right paramedial incision of considerable extent, pushing the peritoneum and the abdominal contents toward the left and obtaining a direct view of the vena cava and its branches from in front. Others have approached the vena cava transperitoneally. One must also realize that in some cases so enormous an amount of blood is trapped in the lower half of the body by sudden interruption of the vena cava that patients are occasionally thrown into serious or even fatal shock unless elevation of the legs is immediately and persistently employed.

Altogether, the operation has many times appeared to be life-saving but should not be undertaken by those not familiar with the difficulties of handling large blood vessels under a variety of circumstances.

This concludes the case for the surgical interruption of veins in the control of thrombosis and embolism. That for the anticoagulants is now to be presented. Special considerations, as in the case of fractures, will be taken up separately.

(To be concluded)

CASE 32311

PRESENTATION OF CASE

A fifty-three-year-old man entered the hospital with jaundice

For several years the patient had had slight postprandial gaseous indigestion produced by fatty foods, this was seldom troublesome, since he had been on a low-fat, low-protein diet because of gout of thirteen years' duration. He had taken colchicine during exacerbations of the disease, with great relief. One and a half years before admission he had the first attack of a colicky right-upper-quadrant pain, after which there was no further difficulty until six months before admission, when he had several episodes of similar pain. At that time a cholecystectomy was performed at another hospital. The gall bladder contained numerous stones. The common duct could not be identified. Postoperatively the patient became jaundiced and began draining large quantities of bile through a laterally placed stab wound. Six weeks later he was re-explored by another surgeon. Again the common duct could not be found. The portal vein was accidentally opened, and the patient lost a great deal of blood. Postoperatively bile drained through the wound, and the previous sinus closed. The jaundice disappeared. Subsequent to the first operation the stools had been acholic, but they turned brown after the second operation. Bile continued to drain until six weeks before admission, when the second sinus closed. Three weeks later the skin became mildly jaundiced and began to itch. Four days before admission there was pain in the right upper quadrant and in both shoulders. This was not related to respiration. During the following three days the patient vomited everything taken by mouth. He continued to have pain and passed scanty, dark urine. The stools were small and slate gray.

Physical examination showed moderate jaundice and slight diffuse tenderness in the right and left upper quadrants. The site of the previous sinus was extremely tender. There were diminished breath sounds and crackling inspiratory and expiratory rales at both lung bases.

The temperature was 97°F, the pulse 100, and the respirations 24. The blood pressure was 100 systolic, 60 diastolic.

The white-cell count was 22,300. The urine was dark amber and gave a + reaction for bile. X-ray films revealed linear bands of density at both lung bases. The upper lung fields were clear. The diaphragm was high on both sides. A film of the abdomen showed the common and hepatic bile ducts to be filled with gas (Fig 1), no dilated loops of bowel were seen.

One hour after admission the patient began to have severe, agonizing left-upper-quadrant pain and quickly developed marked tenderness and spasm of the entire upper abdomen, particularly in the left upper quadrant. Peristalsis was high pitched and hyperactive, alternating with long periods of silence. He was writhing with pain when examined.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR FIORINDO A SIMEONE I think it might be interesting to see the x-ray films first.

DR JAMES R LINGLEY This is a film of the chest showing the high diaphragm on both sides, with linear bands of density at the bases consistent with atelectasis. This plain film of the abdomen shows a moderate quantity of gas in what looks like the colon, which does not appear to be appreciably dilated. This is the gas bubble of the stomach, and in the right upper quadrant it can be seen that the common bile duct, the hepatic duct and the radicles are completely filled with gas. There is no definite mass, and no evidence of stone.

DR SIMEONE I should like to discuss this case from the point of view of complications following the removal of a gall bladder for stones. The patient had postprandial gaseous indigestion produced by fatty foods, and a diagnosis of cholelithiasis was made, for which an operation was performed. He had gout of some twelve years' duration and took colchicine. I thought of the possible lesions associated with gout, but could not find any to account for the symptomatology before or after operation, nor could I find anything that suggested a toxic reaction to the occasional taking of colchicine during a few exacerbations of gout. The gout and colchicine may therefore be considered as purely incidental.

A year and a half before admission the patient had the first attack of colicky pain in the right upper quadrant, so that if this was gallstone colic he had his first attack at the age of fifty-one, which is perhaps slightly unusual but not too much so. Following that one attack he had no more trouble. If he had stones they were silent until six months before admission, when he had several episodes of similar colicky pain in the right upper quadrant, which probably appeared at frequent intervals, suggesting a stone in the common duct, although there is nothing in the record about nausea, vomiting, jaundice or chills and fever. Cholecystectomy was performed at another hospital, and the gall bladder was described as containing numerous stones. It

would be helpful if one knew, in addition to the number of stones, how large they were. Although at operation the common duct could not be found, presumably it was looked for, as indicated by the note that the common duct was not found. I am left with the impression that the stones were smaller than the caliber of the cystic duct, which led the surgeon to look for the common duct.

Postoperatively the patient became jaundiced and began draining large quantities of bile through a laterally placed stab wound. This, of course, brings up a problem that is generally feared in gall-

anomalous and therefore difficult to recognize, or was located in densely scarred gastrohepatic omentum and difficult to dissect and identify. At the second operation the portal vein was accidentally opened, and the patient lost a great deal of blood. We are not told what happened at the second operation, but I imagine that little more was done after the puncture of the portal vein. I suspect that the accident occurred early in the operation, probably before the surgeon had a chance to mobilize the duodenum to identify the common duct transduodenally, this procedure might have favored the

FIGURE 1 *Roentgenogram of Abdomen*

bladder surgery, namely, injury to the common duct. In removal of the gall bladder the common duct is sometimes injured through outright carelessness, less often it is injured because of one of several anatomic anomalies of which the surgeon is not aware until too late. Although this is the first accident to suspect in this case, two points in the subsequent history make me doubt such a diagnosis. In the first place, the roentgenogram showed a common duct filled with air. Secondly, jaundice disappeared and bile appeared in the stools, suggesting that the common duct re-established continuity with the duodenum or other part of the bowel spontaneously after the second operation, which was done because of the jaundice and because of the persistent bile-draining sinus six weeks after the first operation. Again, the common duct could not be found. Perhaps the stricture had been resected or was

establishment of a fistula between the bile ducts and duodenum. It is difficult to understand how the surgeon opened the portal vein without encountering the common duct, because of the anatomic relations of the two structures.

Postoperatively bile drained through the wound, the persistent sinus eventually closed, and the jaundice apparently disappeared, because a new external fistula was formed from the common duct, or perhaps the old fistula was cut across and drained through the wound. The stools turned brown after the second operation, however, so that bile must have been getting into the intestines. I should like to explain that on the basis that at the time of the first cholecystectomy the patient probably had a stone in the common duct as well, which did not cause jaundice until after the operation and somehow became dislodged temporarily after the second

Subsequent to the first operation the stools had been acholic, but they turned brown after the second operation. Bile continued to drain until six weeks before admission, when the second sinus closed. Three weeks later the skin became mildly jaundiced and began to itch. Four days before admission there was pain in the right upper quadrant and in both shoulders. This was not related to respiration. During the following three days the patient vomited everything taken by mouth. He continued to have pain and passed scanty, dark urine. The stools were small and slate gray.

Physical examination showed moderate jaundice and slight diffuse tenderness in the right and left upper quadrants. The site of the previous sinus was extremely tender. There were diminished breath sounds and crackling inspiratory and expiratory rales at both lung bases.

The temperature was 97°F, the pulse 100, and the respirations 24. The blood pressure was 100 systolic, 60 diastolic.

The white-cell count was 22,300. The urine was dark amber and gave a + reaction for bile. X-ray films revealed linear bands of density at both lung bases. The upper lung fields were clear. The diaphragm was high on both sides. A film of the abdomen showed the common and hepatic bile ducts to be filled with gas (Fig 1), no dilated loops of bowel were seen.

One hour after admission the patient began to have severe, agonizing left-upper-quadrant pain and quickly developed marked tenderness and spasm of the entire upper abdomen, particularly in the left upper quadrant. Peristalsis was high pitched and hyperactive, alternating with long periods of silence. He was writhing with pain when examined.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR FIORINDO A SIMEONE I think it might be interesting to see the x-ray films first.

DR JAMES R LINGLEY This is a film of the chest showing the high diaphragm on both sides, with linear bands of density at the bases consistent with atelectasis. This plain film of the abdomen shows a moderate quantity of gas in what looks like the colon, which does not appear to be appreciably dilated. This is the gas bubble of the stomach, and in the right upper quadrant it can be seen that the common bile duct, the hepatic duct and the radicles are completely filled with gas. There is no definite mass, and no evidence of stone.

DR SIMEONE I should like to discuss this case from the point of view of complications following the removal of a gall bladder for stones. The patient had postprandial gaseous indigestion produced by fatty foods, and a diagnosis of cholelithiasis was made, for which an operation was performed. He had gout of some twelve years' duration and took colchicine. I thought of the possible lesions associated with gout, but could not find any to account for the symptomatology before or after operation, nor could I find anything that suggested a toxic reaction to the occasional taking of colchicine during a few exacerbations of gout. The gout and colchicine may therefore be considered as purely incidental.

A year and a half before admission the patient had the first attack of colicky pain in the right upper quadrant, so that if this was gallstone colic he had his first attack at the age of fifty-one, which is perhaps slightly unusual but not too much so. Following that one attack he had no more trouble. If he had stones they were silent until six months before admission, when he had several episodes of similar colicky pain in the right upper quadrant, which probably appeared at frequent intervals, suggesting a stone in the common duct, although there is nothing in the record about nausea, vomiting, jaundice or chills and fever. Cholecystectomy was performed at another hospital, and the gall bladder was described as containing numerous stones. It

tried to repair the duct, but in attempting to make the exposure the portal vein was entered and the operation had to be terminated after a stormy time on the operating table. The patient gradually recovered, and was finally slated to come to this hospital for repair at an optimum time. The surgeon called, however, and said that if the patient did not get into the hospital within three or four days, he would be dead at home. Consequently, he entered the hospital as an emergency case and was rather ill when first examined. A few hours after entry, having been previously quite comfortable, he began to have severe, agonizing, colicky abdominal pain, with high-pitched peristalsis. An x-ray plate was made, and the report that we received was that there was gas in the liver radicles and also dilated loops of small and large bowel. The radiologist in charge that night thought that this represented intestinal obstruction. The gas in the biliary tract, we thought, probably entered from a spontaneous fistula into the duodenum, although the possibility of a transverse-colon fistula had to be considered. Since the pain was colicky and because of the dilated loops of bowel and the fact that the abdomen quickly became tender throughout, we thought it most probable that he had developed a strangulating obstruction, although as a second possibility imminent perforation of an abscess through the liver into the peritoneal cavity near the common duct was considered.

A right-upper-quadrant incision was made. No evidence of intestinal obstruction could be demonstrated. On coming down to the region of the foramen of Winslow we found pus that had a foul odor, indicating that an abscess was perforating at this point. We assumed that it was coming from the liver or from the common duct. We were able to open into the hepatic bed and, finding the stump of the common duct, to insert a T tube into the common duct and into the viscus that was adherent at the portal fissure. The patient's condition was poor at operation. He drained bile for twenty-four hours freely through the tube. The bile was followed by pus and then by fecal drainage. He never really improved, and died almost on the same schedule as his doctor had predicted.

CLINICAL DIAGNOSES

Small-bowel obstruction
Cholechojejunal fistula
Obstructive jaundice
Pulmonary atelectasis

DR SIMEONE'S DIAGNOSES

Residual stone in common duct
Acute pancreatitis

ANATOMICAL DIAGNOSES

Benign stricture of common bile duct
Cholechooduodenocolic fistula

Multiple abscesses, hepatic, subhepatic and diaphragmatic

Acute fibrinopurulent pericarditis

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY Autopsy showed a complicated picture. There was a double fistula from the remnants of the common duct, one went into the duodenum, and the other into the hepatic flexure of the colon. There were two benign strictures in the common duct, one above and one below the area of the fistulas. There was also a communication into a hole in the liver, which was probably an abscess cavity, and led to the left hepatic duct. A small old abscess was found in the region of the head of the gall bladder. There were dilatation of all the intrahepatic bile radicles, multiple abscesses throughout the liver and a considerable subhepatic abscess. Infection had extended into the diaphragm, which was split into two leaves by a collection of pus. There was also acute fibrinopurulent pericarditis. We could not find persisting stones anywhere, and the pancreas — surprisingly enough, in the face of all this biliary infection — showed no trace of inflammation.

DR BENEDICT I do not see how the agonizing left-upper-quadrant pain is explained.

DR WELCH I thought that was explained at the time of the autopsy, because in dissecting between the leaves of the diaphragm we found this great abscess, which must have contained 500 cc of pus. The pus was entirely above the peritoneum and was not in the pleura. It finally perforated into the pericardium.

CASE 32512

PRESENTATION OF CASE

A fifty-nine-year-old housewife entered the hospital complaining of pain in the epigastrium.

Five years before admission the patient, who had previously had fair digestion and no abdominal pain, suffered a severe hematemesis. Thereafter there was almost continuous epigastric discomfort. When she worked too hard or stretched, pain developed in the upper abdomen. There was no further vomiting or passage of black stools after the original episode. One month before admission a severe mid-epigastric pain doubled the patient and required morphine for relief. It radiated slightly to both sides. From then on she had continuous nagging pain, without other symptoms. During this period

operation. Stones in the common duct are not an unusual finding in cholelithiasis. In 1940 Allen and Wallace¹ reported that in a series of 860 cases in this hospital during a four-year period roughly 1 out of 5 patients with cholelithiasis had stones in the common duct and that in almost half (46.8 per cent) the cases in which the common duct was explored, stones were found. It is therefore not unlikely that this patient with numerous stones in the gall bladder had a stone in the common duct, which was not found at the first operation.

Bile continued to drain until six weeks before he was admitted to this hospital, where the second sinus closed. Three weeks before admission the skin became mildly jaundiced and itched. For three weeks, then, the patient had no external biliary fistula and no jaundice. Four days before admission there was pain in the right upper quadrant and in both shoulders. This was not related to respiration. For the next three days the patient vomited everything that he took by mouth. That could have been due to recurrent common-duct obstruction from stone or a leak through the old biliary sinus, and a subhepatic abscess, with pressure on the duodenum, might have formed. He continued to have pain and passed brown stools. Apparently bile was still reaching the intestine.

The diminished breath sounds and crackling inspiratory rales are accounted for by the elevated diaphragm, which resulted from inflammation beneath it and which caused atelectasis in both lower lobes. Physical examination showed diffuse tenderness in the right and left upper quadrants, suggesting an inflammatory lesion in the upper abdomen, but the temperature was recorded as 97°F, so that unless this man was in extremis as a result of the infection, he was not showing the expected temperature rise, which may be taken as evidence against a subhepatic abscess. The pulse was rapid, and the blood pressure low. These findings, along with the low temperature, suggest several possibilities. Perforation of a malignant or benign lesion of the stomach is unlikely. The roentgenogram of the abdomen did not suggest mechanical intestinal obstruction, which should be considered because special mention is made of intermittent high-pitched peristalsis. The history is consistent with mesenteric thrombosis, but again there was no x-ray evidence of intestinal obstruction. The temperature, white-cell count and blood pressure are consistent with mesenteric thrombosis or with acute pancreatitis. The history of repeated abdominal operations, with some inevitable infection, favors the former, the jaundice and cholelithiasis and the suspicion of choledocholithiasis favor the latter.

If the presence of an intact common duct is accepted, the x-ray finding of gas in the biliary tree is difficult to explain. The most plausible explanation for such gas is a fistula between the bile ducts and the duodenum. No evidence of injury to the du-

odenum, which might have favored the establishment of such a communication, was found, and no mention is made of digestion of the skin about the draining sinuses. In rare cases, gas regurgitates into the biliary tree through the papilla of Vater.² In one case these ducts filled with barium during an examination of the stomach for carcinoma, which made me think that the final episode was a perforation of a cancer of the stomach, but there is nothing in the history to indicate such a diagnosis. Cases have been encountered with regurgitation of air and injected barium through the papilla of Vater when a stone has been impacted in the papilla.² I should like to explain the course of events in this patient on that basis. The acute episode of severe agonizing left-upper-quadrant pain could have been due to acute pancreatitis secondary to stone in the ampulla. My final diagnosis is therefore residual stone in the common duct, with acute pancreatitis.

DR EDWARD B. BENEDICT: How about a stone in the pancreatic duct?

DR SIMEONE: I do not believe that that would produce jaundice unless it were close to the junction with the common duct.

DR BENEDICT: I mean in addition to the pancreatitis. Such stones are often demonstrated by x-ray.

DR TRACY B. MALLORY: Does one ever have pain with stone in the pancreatic duct? There is no muscle in the duct, and I do not see how it could go into spasm.

DR SIMEONE: Cases with calcification have been reported in the head and body of the pancreas, with excruciating pain, which is relieved by subtotal pancreatectomy.

DR MALLORY: Pancreatitis would offer a good explanation of the pain, but I doubt that colic can arise from the pancreatic duct.

DR LINGLEY: I do not believe that we have seen gas in the common duct with cancer of the ampulla. Is it not rare?

DR SIMEONE: I think that 5 or 6 cases are reported in the literature with gas in the biliary tree in the presence of an intact common duct and papilla of Vater.

DR LINGLEY: Unfortunately, the cases that we have seen have been due to fistula between the duct and the bowel.

DR CLAUDE E. WELCH: A number of considerations that Dr Simeone has not mentioned troubled me. If I can interpolate a few facts into the history, this may be made clearer. In the first place, there was no question in the mind of the doctor who referred the patient to us that his patient had had an injury of the common duct. Ever since Dr Allen³ published his method for the surgical repair of injuries of the duct, we have been confronted with many of these cases. In the case under discussion, at the time of the second operation, the surgeon

Hodgkin's disease, lymphoblastoma and lymphosarcoma may cause infiltration, with subsequent ulceration of the stomach wall, and it is frequently quite impossible to do more than suspect that a given lesion may be on this basis. But characteristically the picture is that of a rather plastic stomach wall, with overlying, thick and rigid mucosal folds within which the ulceration may be present. Such a lesion does not seem likely.

Areas of ulceration infrequently occurring in gastritis are usually small and multiple, and the findings of gastritis predominant.

Among the granulomas of the stomach in which ulceration occurs, syphilis is most frequently thought of and only rarely seen, as in ulceration in the thickened, stiff and shrunken stomach wall of a so-called "leather-bottle stomach." Ulceration of a gummatous lesion in the stomach is still rarer — enough to be thought of only when nothing else seems to fit the diagnosis and when the serologic findings are indicative. More rarely still has ulceration in the stomach, said to be on an acid-fast basis, been described in a patient with pulmonary tuberculosis. In the case under discussion the serologic findings were apparently not incriminating, and the chest was certainly not.

Neoplasms arising outside the stomach that have become adherent to it occasionally cause ulceration of the mucosa, most frequently, perhaps, cancer of the colon, but nothing in this case suggests anything amiss in the colon. Tumors of the pancreas or other abdominal tumors, such as lymphoma, also cause ulceration. The gastric diverticulum that are occasionally seen in the fundus of the stomach should not be mistaken for significant lesions.

This leaves to be considered the two most frequent causes of ulceration of the gastric mucosa: benign ulceration of the stomach and an ulcer due to a cancer of the stomach. The old problem concerning the relation of cancer to pre-existing ulcer will not be discussed. I should like to mention what I think is the real burden of this presentation. I do not want to be an apologist, but it seems well to point out the limitation of the roentgenologist in determining in every case whether or not an ulcer is benign. The limitations are much the same as those imposed on the surgeon when he has the abdomen open and the viscus exposed and on the pathologist when he has only the gross specimen, with the added drawback of his inability to observe small metastases to the liver and regional lymph nodes. Usually the differentiation is quite reliable. There are findings that suggest a malignant lesion, and others that are either equivocal or difficult to assay. As a rule it is easier to say that a lesion is malignant than that it is not. Demonstration of malignant changes have often to await detailed histologic study.

Characteristically a benign ulcer lies on or close to the lesser curvature, but many ulcers in this position have proved to be malignant and others located elsewhere in positions often thought to be unusual for benign ulcers have proved to be non-malignant. The last three simple ulcers on the greater curvature seen in this hospital were benign. The high incidence of malignant changes in peptic ulcers is well known. The size of an ulcer is not a reliable criterion, neither is roughness or smoothness of the base. Irregularity may be due to tumor granulations or food particles. The duration of the disease is also not diagnostic. The course of an ulcer under active management may be helpful: if it heals and leaves no rigidity of the wall, it is quite likely to be benign, but an ulceration in a tumor that heals or fills with tumor or food usually leaves stiffening behind, which represents tumor infiltration. Perhaps the most reliable sign denoting ulceration in a tumor is the actual demonstration of the tumor in which the ulcer lies. A benign ulcer lies or projects beyond the wall of the stomach — the other lies within the projected wall of the stomach intraluminally, giving rise to the so-called "meniscus sign of Carmen." This is not infallible, however. A large inflammatory reactive mass may be mistaken for tumor, or an ulcer in a tumor may penetrate deeply, and the finding is not always easy to demonstrate with complete satisfaction.

Rigidity of the stomach wall about an ulcer such as that in the case under discussion is most frequently, but not always, due to infiltration by tumor, as is also gross deformity of the gastric mucosal folds about an ulcer.

In this case one would like to speculate on the likelihood of a gastric ulcer, atypical in location and for this reason long overlooked, that had recently perforated — possibly into the liver, which lies in contact with this part of the stomach. This could have resulted in the formation of a large inflammatory mass, which was the palpable tumor and which might have been mistaken for the mass about the visualized ulcer. The location was unusual, however, and the ulcer was large, and rigidity of the wall was described. And there was a mass that presented a shelf-like defect — an intraluminal tumor in which the ulcer was situated. And since no subsequent examination demonstrated this to be a faulty observation, it must be accepted.

The diagnosis of leiomyosarcoma still intrigues me, in spite of the fact that the x-ray findings are not typical. The story is not inconsistent with cancer of the stomach, which is by far the most frequent tumor. The x-ray findings gave evidence of some kind of tumor. This all leads to a diagnosis — admittedly based largely on a single examination — of ulceration in a cancer of the fundus. The safest thing, of course, would be to say an ulcerating lesion of the stomach that was not conclusively benign.

the patient had been on a Sippy regime. There was a recent weight loss of 9 pounds from her normal weight of 107 pounds. Numerous x-ray films were taken during her illness, including a gastrointestinal series six months and a chest film two weeks before admission, which were said to be negative. Because it was thought to emanate from the spine the pain was treated by a back brace. She had had slight low-back pain, attributed to rheumatic changes shown in x-ray films of the spine. There had been no jaundice or acholic stools, constipation, diarrhea or distention.

The past history was not remarkable, except for the implantation of radium per vagina for menorrhagia at the menopause, thirteen years before admission.

On physical examination there was a firm, non-tender mass in the epigastrium, which moved with respiration and transmitted a powerful aortic pulse. Both kidneys were palpable.

The temperature was 98.0°F, the pulse 70, and the respirations 18. The blood pressure was 160 systolic, 90 diastolic.

The hemoglobin was 10.2 gm per 100 cc of blood. The white-cell count was 10,600. The urine was normal. The stool was light brown and gave a negative guaiac reaction. X-ray studies revealed a crater, 3.0 by 2.5 by 2.0 cm, in the posterior wall and lesser curvature of the stomach just below the cardia. It appeared to be in a filling defect, the upper margin of which was somewhat shelf-like. The remainder of the stomach showed rather small peristaltic waves, without definite evidence of rigidity except for an area about 3.0 cm below the lower margin of the lesion. The duodenum and the rest of the intestine were normal. One hundred cubic centimeters of fluid aspirated from the fasting stomach contained 3 units of free hydrochloric acid per cubic centimeter; there was no free hydrochloric acid in the 8-cc specimen after alcohol. An electrocardiogram was normal.

A gastroscopy was done on the tenth day. The instrument was blocked at the cardiac orifice, but it was possible to see beyond the obstruction to the lesser curve, where a 3-cm ulcer was visible on the anterior wall. It had slightly irregular margins and a sloughed base.

Operation was performed on the twenty-sixth hospital day.

DIFFERENTIAL DIAGNOSIS

DR MILFORD D SCHULZ. This is the story of a patient presenting a complaint of abdominal discomfort and pain of which she had not been entirely free for five years. The first episode was accompanied by hematemesis, which was not repeated. She had received treatment intended to control a peptic ulcer, although there had never been visible evidence of a gastric or duodenal lesion until after the acute episode a month before ad-

mission, when further study of the upper gastrointestinal tract with the help of a roentgenologist and an endoscopist demonstrated a large ulcerating lesion high on the stomach wall. The variance of opinion regarding whether the lesion was on the anterior or posterior wall is understandable when one considers the problems of orientation in this area.

This problem resolves itself into the differential consideration of ulcerating lesions of the stomach.

Since I should like to discuss this case mainly from the standpoint of a roentgenologist, a review of the x-ray findings might be helpful. The ulcer, which was 3 cm in size, was unusually high and although not on — but toward — the lesser curvature, it seemed in fact to be above the lesser curvature and in the fundus. The ulcer did not appear to protrude beyond the stomach entirely but rather to lie intraluminally as though in a mass about which a so-called "shelf" was described. This was probably the fluoroscopist's observation and is most important. It is certainly not an observation, however, that cannot be wrong, for the fundus is sometimes difficult to examine satisfactorily. No abnormality of peristalsis was demonstrated, although some rigidity was described just below the crater. Again, when the lesion is beyond the reach of the palpating hand, this observation is uncertain. The mucosal pattern did not seem to be altered, except in the immediate vicinity of the crater, where the appearance of convergence of folds toward the ulcer may have been merely apparent, owing to the projection of the fundus. No soft-tissue mass outside the projected wall of the stomach was demonstrated.

Tumors of the spindle-cell variety may be benign or malignant, are slowly growing and often ulcerate, sometimes quite early, leading to abrupt and intermittent bleeding, which may be the only presenting complaint. The history in this case is not incompatible with such an occurrence. But these tumors lie in the wall of the stomach and grow submucosally, more or less equally in all directions, stretching and bulging the stomach wall into a smooth crescentic defect over which the folds of an intact mucosa are smoothed out except where the usually somewhat centrally placed ulcer extends into the large, rounded soft-tissue mass outside the wall of the stomach, which can occasionally be seen on adequate x-ray films. A spindle-cell tumor is suggested by the long history, with early and non-continuous bleeding, by the palpable mass, and by the recent episode after which a previously undiscovered ulcer was found, which may have meant recent ulceration, furthermore, an un ulcerated extramucosal spindle-cell tumor in this position can easily be overlooked. Since none of the characteristic x-ray findings were present in this case, I shall dismiss this diagnosis. It might still be entertained, however, as an outside chance.

HOSPITAL CARE OF VETERANS

ELSEWHERE in this issue of the *Journal* there appears a report from the secretary of the Deans' Committee of Harvard, Boston University, and Tufts College medical schools concerning the status of the Veterans Administration Hospital in West Roxbury. Representatives of these three schools have undertaken to provide the resident, attending and consulting staffs of this institution with the view of making it into a hospital that will be recognized as acceptable for resident training not only by the American Medical Association but also by the various specialty boards. In addition, it is anticipated that the same procedure will follow when the 2000-bed Cushing General Hospital in

Frammingham is turned over to the Veterans Administration

All this is in accordance with plans laid down by General Omar Bradley and by Dr Paul R. Hawley, former chief surgeon for the European Theater of Operations and now chief medical director of the Veterans Administration. The project is a great step forward, primarily, of course, it guarantees better care of the veteran, but it also provides a method of giving further hospital training to the large number of young doctors in the armed services who had a much-shortened period of medical-school and intern education. The affiliation of the Veterans Administration hospitals with medical schools is coming into effect throughout the country, and the impression has already been gained that an increased turn-over of patients has resulted—in other words, the average length of time required to treat veterans has been reduced because of the improved situation regarding medical service and personnel.

There can be no doubt that this plan, energetically pursued, will result in great benefit to veterans, to recently graduated physicians and, because of reduced costs resulting from better medical care, to the public at large. There is much work yet to be done, but certainly if the profession co-operates wholeheartedly and sympathetically, this forward step in caring for the enormous and unavoidable by-product of war will result in improvement in the handling of one of the major medical and sociologic problems of the country.

"IN THY MOST NEED"

THE Institute of Pastoral Care, established at the Massachusetts General Hospital in 1944, had its beginnings in an address delivered by Dr Richard C. Cabot over twenty years ago entitled "A Plea for a Clinical Year for Theological Students." Out of this plea came the establishment of a training course at the Worcester State Hospital in 1924 and, in the belief that a broader experience could be gained from a general hospital, the beginning of a continuing program at the Massachusetts General Hospital in 1933.

DR EDWARD B BENEDICT The gastroscope met with complete obstruction at the cardiac orifice. That usually means a carcinoma, but in a case of ulcer high up close to the cardia with spasm, the gastroscope may meet with complete obstruction. The ulcer itself looked irregular, in spite of a smooth margin. That observation has been slightly in favor of cancer, although severe gastritis around an ulcer may produce a similar effect. I thought from the gastroscopic standpoint that the ulcer was probably malignant, although the five-year history seemed rather long. It seems to me in any of these cases that the important thing to decide is not whether or not the lesion is benign but whether or not to operate. I should rather operate on a benign ulcer erroneously than to let a malignant ulcer go without operation. The decision was therefore made to operate on this patient.

CLINICAL DIAGNOSIS

Carcinoma of stomach?
Gastric ulcer?

DR SCHULZ'S DIAGNOSIS

Ulcer in cancer of stomach

ANATOMICAL DIAGNOSIS

Benign peptic ulcer

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY This patient was operated on by Dr Richard H Sweet via the trans-thoracic route, which is obviously indicated with a lesion as high in the cardia as this one was. He found a very indurated mass in the stomach, which was densely adherent to the pancreas. He carefully searched the abdominal cavity but found no evidence of metastases. He was still uncertain whether the lesion was benign or malignant, but believed that it was readily resectable and proceeded with the operation. The only difficulty met with was in dissecting it free from the pancreas. The microscopic sections showed a benign peptic ulcer, with no evidence of neoplasm.

The unusual points in the case have been brought out by Dr Schulz: this lesion was much higher in the stomach than benign ulcers are usually found, and the area of ulceration was considerably larger than that ordinarily seen with benign ulcers. There is essentially no limit to which a benign ulcer can reach, however. I have seen one 10 cm in diameter, three times as large as the one in the case under discussion.

ishment *Provided*, that such person is supplied with a written statement from the patient's physician or, in the case of an establishment engaged in the care and treatment of the sick, from a responsible official thereof who is a practicing physician, and such written statement shall be valid for a period of not to exceed sixty days from the date of issuance and shall specify (i) The milk fat content of cream required for such use, (ii) the daily quantity of such cream, and (iii) with regard to the necessity of such cream for supervised medical treatment *Provided further*, that such written statement shall not be valid for obtaining such cream unless approved by a public health officer who is a physician, or by the secretary of the county medical society of the county wherein such patient resides or such establishment is located

2 Upon application by one or more persons in any area or region and after demonstration to the satisfaction of the Administrator that compliance with the provisions of (b) (1) hereof will not tend to conserve milk fat for defense and essential civilian needs, or upon the initiative of the Administrator, the Administrator may grant an exemption from the provisions of (b) (1) hereof to any or all persons in such area or region specified by the Administrator

Finally, any person who feels aggrieved by this regulation may file a petition for relief with the War Food Order Administration and send his or her communication to the War Food Order, No 149, Dairy Branch, Production and Marketing Administration, United States Department of Agriculture, Washington 25, D C

MICHAEL A TIGHE, M D, *Secretary*

DEATHS

CHANDLER — Harold B Chandler, M D, of West Newton, died July 14 He was in his sixty-first year

Dr Chandler received his degree from Harvard Medical School in 1911 and had limited his practice to ophthalmology His widow, two daughters and a son survive

ELMS — Evelyn B Elms, M D, of Waban, died July 14 She was in her fortieth year

Dr Elms received her degree from Tufts College Medical School in 1932 She served as a lieutenant in the Navy Medical Corps during World War II and was a fellow of the American Medical Association

Her mother and a brother survive

CORRESPONDENCE

RESIDENCY TRAINING IN MASSACHUSETTS VETERANS ADMINISTRATION HOSPITALS

To the Editor The establishment of a Department of Medicine and Surgery in the Veterans Administration, as provided for under Public Law 293, has led to the development of an extensive residency training program in many Veterans Administration hospitals It is hoped that this program will result in securing for the veteran patient a standard of medical and surgical care comparable with that rendered in the best civilian hospitals To secure the best advice and assistance in carrying out such a program, the Veterans Administration has called on the deans of schools of medicine to give counsel in all matters pertaining to the education and training of residents and is, with the help and advice of the deans, appointing qualified staffs of part-time civilian specialists These specialists will carry on much of the residency training

The Deans' Committee for the Massachusetts Veterans Hospitals consists of Dean Dwight O'Hara of Tufts College Medical School, chairman, Dean C Sidney Burwell of Harvard Medical School, Dean Donald G Anderson of Boston University School of Medicine and Dr Dale Friend, of Harvard Medical School, secretary Each dean has selected two advisors, one in medicine and one in surgery These

advisors are Drs Laurence B Ellis, James M Faulkner, Roger C Graves, Chester S Keefer, Reginald H Smithwick and Augustus Thorndike

Part-time civilian specialists are divided into two categories depending on the degree of experience and skill, teaching qualifications and need The first group consists of senior physicians of outstanding ability — those of professional caliber in the medical schools or of equivalent standing among the practicing profession of the community These men are called consultants They assist and advise the chief of the service in the veterans hospital concerning organization, care of patients and appointment of residents and take a prominent role in the teaching of residents by ward rounds, seminars, clinics and demonstrations They are also available, to the hospital for consultation in all matters relating to their specialties as applied to the care and treatment of patients It is desirable that consultants be certified by their specialty board and be veterans of either World War I or World War II They must be approved by the Deans' Committee The number of visits is regulated by the needs of the particular hospitals The second group consists of younger physicians of proved ability who are members of medical-school staffs or have an equivalent standing in the practicing profession of the community These men are called attendings They actively participate in the care of patients by conducting ward rounds, performing operations and carrying out such other therapeutic measures as may be required They also assist and advise in the organization of services and take a prominent role in teaching residents The chief of the service delegates much of the care of the patients to these men The Veterans Administration, of course, is responsible for the care and treatment of patients, but the chief of service, as the representative of the Veterans Administration, delegates responsibilities according to the merits of the case The attendings participate in clinics, seminars and demonstrations and assume a great deal of the teaching load They must be certified by their specialty board, be veterans of World War II and be approved by the Deans' Committee The number of visits vary according to the needs of the hospitals

Physicians accepted for residency training must be graduates from approved medical schools and veterans of World War II, must have the intention and ability to go on to specialty-board certification and must be approved by the Deans' Committee

The Veterans Administration hospitals at present interested in the residency training program are those located in Bedford, Rutland Heights and West Roxbury The West Roxbury Hospital has been actively studied by the Deans' Committee, and a qualified staff has already been appointed It is anticipated in the near future that this hospital will have the approval of the various specialty boards as a suitable institution for residency training The newly appointed staff consists of the following physicians

This program was inaugurated under the leadership of Reverend Russell L. Dicks, and it has been continued and finally organized into the present new institute under the immediate direction of Reverend Rollin J. Fairbanks, Protestant chaplain of the hospital. On the Board of Governors are represented theological schools, hospitals, the Massachusetts and Michigan councils of churches and the Ella Lyman Cabot Trust. Recently the University Hospital at Ann Arbor, Michigan, was selected as the Institute's second training center.

The purpose of the Institute, as set forth in its constitution, is "to organize, develop and support a comprehensive educational and research program in the field of pastoral care, with special reference to the sick, using the opportunities offered by clinical training as a primary means to this end." Pastoral care, it might be stated parenthetically, may be considered as the art of ministering to the individual—to care for like a shepherd in the spiritual sense, and if the Institute can achieve its goals, the preventive phase of pastoral care will also be fully developed.

For the summer of 1946 three training sessions are available—two at the Massachusetts General Hospital, limited to an enrollment of twenty men each, and one at Ann Arbor, where fifteen theological students or clergymen will be enrolled. The first two weeks of each six-week course are devoted by its participants to half-time work as orderlies on the hospital wards. Many clinical phases of hospital experience are observed, daily seminars are held, and lectures are given on pastoral, medical, psychiatric and social-service problems. At the end, the student, whether he be a young theologian or a minister with years of church work behind him, will have gained experience in human relations and will be better equipped to embark on or resume the pastoral work of his own parish.

It is heartening to realize that organized religion, without which the human community can hardly function properly, has not irrevocably jelled into any outworn form but has retained within itself the capacity of remolding its ministrations to fit the needs of human kind. It might be well if the student of medicine, at any stage in his life-long task of learning, could also visit for awhile with the pastor

and review the humble doctrines of ministering to the spirit. Each profession, indeed, assumes to no small degree the role of Knowledge in the moral play of "Everyman."

**Everyman, I will go with thee, and be thy guide,
In thy most need to go by thy side**

MICHAEL A. TIGHE, *Secretary*

DISTRIBUTION AND SALE OF HEAVY CREAM

The following is submitted for the information of the readers of the *Journal*:

On June 26, 1946, the United States Department of Agriculture issued a directive (WFO 149, Part 1401-Dairy Products), which has to do with the distribution and sale of cream.

This directive, which became effective on July 1, 1946, prohibits the distribution and sale of cream, except to handlers, that is higher than 19 per cent in its fat content, except in those states in which the local law defines cream as containing a minimum of more than 19 per cent fat, 20 per cent being the maximum allowed.

The Massachusetts law requires that cream that is to be offered for sale within the confines of the Commonwealth shall contain 16 per cent fat as a minimum. Under this directive, the milk handlers in Massachusetts may therefore offer for sale only cream that is not in excess of 19 per cent fat, subject to the following exceptions:

- 1 Any person may sell or deliver to or for any patient, or to any establishment engaged in the care and treatment of the sick, cream of such milk fat content, and in such quantities, as may be necessary for supervised medical treatment of such patient or the patients of such establishment.

SCHISTOSOMIASIS JAPONICA

Diagnosis and Treatment in American Soldiers

MAJOR PORTER K. MASON, M C, A U S, COLONEL WORTH B. DANIELS, M C, A U S,
CAPTAIN FRANKLIN K. PADDOCK, M C, A U S, and MAJOR HARRY H. GORDON, M C, A U S

FOLLOWING the invasion of Leyte, an island in the Philippines, on October 20, 1944, cases of schistosomiasis japonica began to appear among Army personnel. It is the purpose of this report to describe briefly the results of an investigation of 481 patients studied four to nine months after acquiring the disease. The dissemination of this information will enable patients from this and other hospitals who are being discharged from the Army and scattered throughout the country to obtain appropriate care in places where the disease is unknown. Although the results of this study are to be reported separately in considerable detail,¹ it is believed that the information acquired concerning diagnosis and treatment merits wider distribution. Since up to the present no snail capable of acting as an intermediate host for the parasite has been found in the United States,² it is not expected that the disease will be disseminated in this country. The problem therefore resolves itself into one of assuring proper care and follow-up for the small number of soldiers already infected.

THE ACUTE ILLNESS OVERSEAS

Several weeks after exposure, the patients developed chills, sweats, generalized malaise, lethargy, headache, anorexia, mild diarrhea and abdominal pain, with marked weight loss. Urticaria and jaundice were observed in some cases. Examination revealed a slightly enlarged and tender liver and occasionally an enlarged spleen. Leukocytosis with marked eosinophilia was usual. In some asymptomatic cases suspected of the disease because of eosinophilia, the ova of *Schistosoma japonicum* were found in the stools. In 8 of the 481 patients considered at this hospital to have had schistosomiasis japonica, there were weakness of the extremities and reflex abnormalities that followed an encephalomyelitis in the acute phase of the disease.

In about three fourths of the patients the ova of *Schistosoma japonicum* were found in the stools.

Fuadin was given to almost all the patients treated overseas, the usual amount given being approximately 40 cc. In some cases a second course of the drug was given. Tartar emetic, in a concentration higher than that employed at this hospital, was used in a small number of cases.

THE DISEASE AS SEEN IN THE UNITED STATES

Four to nine months following their acute illness, patients were evacuated to this country for further study. On arrival at this hospital, they were convalescent and did not appear ill. The only abnormalities that appeared to have some specificity were recurrent cramps and tenderness in the upper abdomen. A slightly enlarged liver was felt in 10 per cent of the patients.

During the period of observation here, which lasted for three months or more, the patients tended to improve clinically whether or not their stools were demonstrated to contain ova. On discharge almost all the patients were free of signs and symptoms of the disease and had no disability preventing unlimited activity. They were advised, however, to have their stools examined every three months for a period of one year for reasons given below.

EXAMINATION OF STOOLS

The stools were examined over a period of at least two weeks initially and after two furloughs of thirty and twenty days, respectively. Patients untreated at this hospital because of repeatedly negative stools were released after an average of twenty-two stool examinations over a period averaging four months.

Methods

Stools were examined in all patients by multiple direct smears and in some by concentration methods. Although multiple direct smears detected the vast majority of positive stools, in a small number one or another of the sedimentation methods was necessary.

In addition to the above appointments the following physicians have accepted full-time positions in the Veterans Administration and have been assigned to the West Roxbury Hospital

Dr John Houghton	Chief of pathology
Dr D Littman	Cardiology
Dr John Poutas	Clinical director
Dr J L Rudd	Physical medicine and rehabilitation
Dr Samuel Tartakoff	Chief of neuropsychiatry
Dr Richard Warren	Chief of surgery
Dr Thomas Warthin	Chief of medicine
Dr Egon Wissing	Chief of roentgenology

Preliminary studies have been made of the needs of the Neuropsychiatric Hospital at Bedford. The Neuropsychiatric Subcommittee, consisting of Dr Harry Solomon, of Harvard Medical School, chairman, Dr William Malamud, of Boston University School of Medicine, and Dr Clifton Perkins, State Commissioner of Mental Diseases, is at present formulating plans for training at Bedford. The following part-time physicians have been appointed to the staff at Bedford: Dr Douglas Thom, consultant in neuropsychiatry, Dr Sylvester B Kelley, consultant in urology, and Dr Jackson Thomas, attending in neuropsychiatry. Dr Norman Elton is chief of pathology and a full-time Veterans Administration appointee. As the needs are more fully ascertained, more part-time appointments will be made and residents will be assigned.

The tuberculosis hospital at Rutland Heights is also under study. Up to the present time little change has been made other than the appointment of Dr L Davenport as consultant in chest diseases and of Dr D Harken as consultant in thoracic surgery.

The Cushing General Army Hospital at Framingham will be taken over by the Veterans Administration on October 1, 1946. The program that has been carried out at the West Roxbury Hospital will be put into effect. It is anticipated that this hospital will have 1000 beds, which will provide many openings for consultants, attendings and residents.

The Dean's Committee is happy to report that it has had excellent co-operation from the Veterans Administration and from the physicians of the region. There is every reason to believe that this program will, as it develops, ensure that the veteran will receive the best available quality of medical care and that it will also provide an excellent opportunity for residency training leading to certification by the various specialty boards.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

The Psychology of Women. A psychoanalytic interpretation. Volume II *Motherhood*. By Helene Deutsch, M.D., associate psychiatrist, Massachusetts General Hospital, and lecturer, Boston Psychoanalytic Institute. 8°, cloth, 498 pp. New York: Grune and Stratton, 1945. \$4.50.

In this second volume Dr Deutsch has completed her work on the psychological life of the normal woman and discusses all the aspects of motherhood.

Local Health Units for the Nation. A report. By Hare Emerson, M.D. With the collaboration of Martha Lubitbuhl, M.A. 4°, paper, 333 pp., illustrated. New York: The Commonwealth Fund, 1945. \$1.25.

This monograph is a report by a committee of state and local public-health administrators whose purpose was to suggest the way to cover a free society with full time health services at the community level.

Fundamentals of Pharmacology. By Clinton H. Thielen, M.D., Ph.D., professor and head of the Department of Pharmacology, School of Medicine, University of Southern California, and attending pathologist (toxicology), Los Angeles County Hospital. *Medical Students Series* 8°, cloth, 497 pp., with 36 illustrations and 19 tables. New York and London: Paul B. Hoeber, Incorporated, 1945. \$5.75.

This new manual in the *Medical Students Series* is a practical and concise text for students and physicians. It contains the essentials of pharmacology brought up to date and correlated with modern therapeutics. Despite its conciseness, valuable clinical material has not been omitted from the text. The author makes use of a simple original classification, discussing in order drugs acting on the central and peripheral nervous systems, those acting on the muscular system, antiparasitics, hormones, iron, tissue extracts, vitamins and drugs having local action on body surfaces, including irritants, cathartics, expectorants and emetics, carcinatives, emollients and demulcents, astringents and antacids. There are also short chapters on chemical diagnostic agents, drug action on cells, pharmaceutical preparations and prescription writing.

All important U.S.P. preparations are described, and a sufficient description of the physical and chemical properties of drugs is given to facilitate writing prescriptions. The major emphasis is laid on the dynamics of drug action, the absorption, distribution, metabolism and excretion of essential drugs and their therapeutic indications.

The text is well written and printed on good paper, with a good type, and a comprehensive, inclusive index ends the volume. The book should prove useful as a ready reference source in its field.

NOTICES

ANNOUNCEMENTS

Dr William B. Coen announces the removal of his office to 111 Maple Street, Springfield.

Dr Armand M. Gamboa announces his return from naval service and the opening of his office at 1075 Boylston Street, Boston.

Dr Nelson R. Saphir announces his return from military service and will resume the practice of internal medicine at Suite 3, Hotel Canterbury, 14 Charlesgate West, Boston.

(Notices continued on page x)

clude its use. Much of this result may be due to too rapid injections or too high a concentration of the solution used. This conclusion is based on the insignificance of toxic reactions found in this study under the conditions outlined below.

With a dilute solution (0.5 per cent) and a slow rate of injection (8 cc a minute), reactions sufficiently severe to justify stopping the drug were encountered in only 2 of the 102 patients treated with more than two thousand injections and carefully observed for evidence of reaction. Seventy-one per cent at one time or another developed a transient hacking cough. Nausea, occasionally associated with vomiting, appeared in 15 per cent. In most cases, the nausea could be diminished by having the patient suck a piece of lemon during the injection. The most striking toxic reaction was a transient sense of soreness, usually in the region of the shoulders, which appeared eight to twelve hours after the injection in 75 per cent of the cases. It did not prevent the patients from being ambulatory.

In all the patients treated with tartar emetic and in half of those treated with fuadin, there appeared a diminution in the size of the T waves in one or more leads of the electrocardiograms, with a complete inversion in some cases.¹⁰ On casual examination these changes were like those seen in coronary thrombosis or pericarditis. With cessation of therapy, the T waves returned to normal. These changes were never associated with any clinical signs or symptoms of cardiac disease, and the drug was not stopped.

Some evidence has been obtained that antimony causes a minor transient impairment of liver function.⁵ It is therefore suggested that in patients who require repeated treatment with antimony compounds, tests of liver function should be performed before, during and after the administration of therapy to determine whether there is any cumulative toxic effect.

No deleterious effect of antimony was noted in the urine or in the cellular constituents of the blood.

Results

One hundred patients with ova of *S. japonicum* in the stools were treated with either fuadin or tartar emetic. The cases were alternated without regard to overseas therapy or to the patients' condition overseas or on arrival here. Additional patients were treated with longer courses of fuadin (105 cc) and tartar emetic (416 cc) at the same individual dose level. These patients are now being followed at another hospital.

After the completion of treatment, the patients were sent on a thirty-day furlough. On their return, follow-up studies were begun. An average of nineteen stools were examined over an average period of three and a half months following treatment before therapy was considered successful. Any patient whose stool was found to be positive at any time

during the follow-up period was given the same course of treatment again and was similarly followed.

The rate of apparent cure (negative stools) in the tartar emetic group was 81 per cent, whereas that for the fuadin group was 18 per cent. In addition, of the 16 cases treated twice with fuadin at this hospital because of continued positive stools and followed for a short period of time, 69 per cent had positive stools for the third time.

Discussion

Schistosomiasis japonica as encountered in these patients offered a unique group for study. The usual textbook picture of this illness is based on the cases in which there has been repeated exposure over a period of years, whereas in this series the maximum length of exposure was only a few months. Furthermore, these patients were healthy soldiers who were given the advantages of prompt treatment.

The most frequent complication in the often exposed native population, owing to the deposition of the eggs, is said to be hepatomegaly and splenomegaly.⁷ In the present series there was little evidence of such changes. Recurrent epigastric pain and tenderness appeared to be the most frequent symptom after the acute phase had subsided, but on discharge there was no evident disability. Whether definite liver disease may develop later if ova continue to be produced is not known. Asymptomatic infections also occurred. Certainly, the possibility should be kept in mind in all persons who were on the east coast of Leyte or in other endemic areas.⁶

Frequent stool examinations by more than one method are required to demonstrate the eggs in the stools. From these studies it is obvious that an occasional observation is insufficient. It is only by repeated stool examinations with multiple methods that eggs will be demonstrated, their discovery leading to the institution of therapy.

Treatment at this hospital with tartar emetic showed better results than did that with fuadin. Furthermore, the toxic symptoms of tartar emetic were for the most part mild. Since, however, the sole criterion of cure is the absence of eggs in the stools, no final conclusion can be drawn until these cases have been followed for many years. Our arbitrary recommendation of one year of follow-up may require alteration in the light of continuing collection of data.

Many of the soldiers showed anxiety about the possibility of developing disability at a later date. Intelligent reassurance can be based only on the taking of steps to guarantee them adequate re-examination and treatment in both the Army and civilian life. It is the purpose of this paper to call attention to this need.

SUMMARY AND CONCLUSIONS

Four hundred and eighty-one cases of schistosomiasis japonica acquired on Leyte, an island in

for detection of the ova. When a modified gravity sedimentation method was made available,³ it was found in a comparative study to add a significant number of positive results.⁴

In the direct smear method, a bit of mucus is taken from the outside of the stool, as being likeliest to contain eggs. This is mixed with a small amount of tap water and mounted under a coverslip. Search of the entire covered area is made through the low-power lens of the microscope, and any suspicious objects are examined under the high-dry lens. Eggs were in most cases readily distinguished under low power. Even under high power, the single laterally placed knoblike spine was rarely seen. Motion of the miracidia could be seen in viable eggs.

In the modified gravity sedimentation method of Barody,³ approximately 5 gm of feces is partially emulsified in 35 cc of tap water by shaking in a 100-cc test tube. The fluid is strained through a single layer of surgical gauze into a 30-cc centrifuge tube and centrifuged at 1000 r p m for one minute. The supernatant fluid is discarded and the sediment is resuspended in tap water. Centrifuging is repeated three or four times until the supernatant fluid is relatively clear. A portion of the final sediment is transferred to a slide, covered and examined microscopically.

Results

Thirty-one per cent of all patients admitted to this hospital with a diagnosis of schistosomiasis japonica had eggs in their stools, and the results of stool findings overseas combined with those obtained here proved conclusively that 80 per cent of these patients had schistosomiasis. In the remainder the clinical history was sufficiently characteristic to warrant little doubt of the diagnosis.

In approximately 10 per cent of the cases found to be positive here, the eggs were not found until the final follow-up period, when a minimum of twelve stools had been examined. In some cases, more than twenty stools were examined before ova were found.

An eosinophilia of 10 per cent or more was found in half the cases on admission here and was associated with the finding of ova in the stools two or three times more frequently than when the eosinophilia was less than 10 per cent. During the follow-up periods, however, an eosinophilia of more than 20 per cent was occasionally encountered even in the cases with repeatedly negative stools. Although not of specific diagnostic value in schistosomiasis because of its presence in other parasitic infections, a persistent eosinophilia demands an even more meticulous search for schistosome eggs.

A variety of liver-function tests done on initial examination showed a 10 per cent incidence of mild impairment.⁵ There was no apparent relation between these abnormalities and the stool findings.

Sigmoidoscopy was done routinely in the first 300 patients. Abnormalities were found in only 3

patients. Since the stools of these patients contained ova on direct examination, this procedure was not helpful in making the diagnosis. Barium enemas in 50 cases were normal.

Of the stools of 463 patients evacuated with a diagnosis of schistosomiasis japonica, those of 146 (31.5 per cent) showed one hundred and seventy-eight infections with seven species of pathogenic intestinal parasites. The incidence of infection in these 146 patients was as follows: hookworm, 16.4 per cent, trichocephalus, 11.4 per cent, *Endamoeba histolytica*, 3.5 per cent, *Ascaris lumbricoides*, 3.2 per cent, Strongyloides, 2.2 per cent, *Hymenolepis nana*, 1.1 per cent, and *Giardia lamblia*, 0.6 per cent.

TREATMENT

The incidence of the failure of treatment as judged by the finding of positive stools in patients treated overseas was found to be definitely lower with tartar emetic than with fuadin. Treatments with these two drugs at this hospital were also compared.

Fuadin

- Fuadin, a trivalent antimony compound, was given in 6.3 per cent solution intramuscularly. Initial doses of 1.5, 3.5 and 5.0 cc were given on successive days, followed by injections of 5.0 cc every other day until a total of 65 cc (0.57 gm antimony) had been given, which required twenty-five days.⁶

Commercial Tartar Emetic

Commercial tartar emetic, also a trivalent antimony compound was given intravenously in the form of a 0.5 per cent solution in 5 per cent dextrose in normal saline solution at a maximum rate of 8 cc a minute. The patient was required to lie down during the injection and for one hour after it. The drug was given every other day. The initial dose was 8 cc, this was increased by 4 cc with each dose until a level of 24 cc was reached. Thereafter 24 cc was given every other day until a total of 320 cc (0.58 gm of antimony) had been given, which required twenty-nine days.

Freshly Prepared Tartar Emetic

Freshly prepared tartar emetic was used as follows. Sufficient potassium and antimony tartrate was accurately weighed with a sterile technic to make a solution of 0.5 per cent in 5 per cent dextrose in normal saline solution. After the solution was prepared, it was heated in a boiling hot-water bath for five minutes and allowed to cool prior to administration. The solution was injected at the same rate and in the same amounts as was the commercial tartar emetic.

Evidence of Toxicity

Judging by the literature⁷ and by certain reports from the Pacific,^{8,9} toxic reactions due to intravenous tartar emetic may be of sufficient severity to pre-

From September, 1943, to the present time there was shipped a total of 698,973 tons of medical supplies, kits, chests and other medical items. In normal times such an operation represents a big job. In wartime, with shortages of many items needed for the production of these supplies and the difficulties in getting the goods transported, the job was accomplished only by fighting every ton of equipment almost every mile of the way from the raw material to medical aid for a wounded man.

Penicillin is a good illustration of the problems that confronted us. Prior to 1943 the world had produced a total of only 1 pound of penicillin. Early in 1945 the original goal of 300,000,000,000 units a month, or 15 pounds a day, was passed. The original price of \$20 a vial was cut to the present figure of approximately 76 cents.

Atabrine was another source of worry. The Allied Nations lost 95 per cent of the world's supply of quinine when the Japanese captured the Netherlands East Indies. Like penicillin, atabrine also introduced what seemed like insurmountable obstacles in the intricate process of manufacture. It takes $2\frac{1}{2}$ tons of chemicals to make 100 pounds of atabrine, a ratio of 30:1. On the surrender of Corregidor there were 35,000,000 tablets on hand and a yearly manufacturing capacity of 227,000,000 tablets. Through heavy pressure from the Medical Department production was boosted so that 3,500,000,000 tablets were produced in 1944, with the cost brought down from \$24 per 1000 tablets in 1940 to \$3 in 1944.

Blood plasma is an interesting item from a supply standpoint. The processing of blood plasma began in February, 1941. Procurement averaged approximately 140,000 units of 250 cc per month, with an all-time high of 178,000 in October, 1944. Shipments of whole blood to Europe started in August, 1944, and continued until May, 1945, with a total shipment of 206,000 pints of Group O blood. To the Pacific, 177,734 pints were flown.

It was through the success of our operations in supply and personnel that we were able to staff, equip and maintain the system of Army hospitals. Overseas in all theaters there were 217 general, 196 station, 99 field, 91 evacuation and 73 portable surgical hospitals. Including convalescent hospitals and centers, there was a total of 692 hospitals overseas at the peak of operations. There were 65 general and 13 convalescent hospitals in the Zone of the Interior. During the war 15,000,000 patients were admitted to Army hospitals for treatment. The peak of the world-wide total load was 544,000 in April, 1945. The peak in Army hospitals in this country was 312,000 in August, 1945.

The American Army in this war was the healthiest in the world. The program of preventive medicine was an important factor in this record. Through the development and use of toxoids and vaccines, fear of tetanus, yellow fever and typhus became

a thing of the past. There were no deaths from these diseases among American soldiers who were inoculated against them.

Malaria at one time incapacitated ten times as many soldiers as did Japanese bullets. Through proper control measures malaria was cut to one fourth its incidence in the early days of the war in the Pacific. Atabrine proved even more satisfactory than quinine. It serves as a suppressive just as quinine does, and also cures the malignant form of disease known as falciparum malaria. The part DDT played in the battle against disease was, of course, a major one. In my tours to overseas theaters I have seen islands, such as Saipan, where there were no traces of mosquitoes or flies as a result of the spraying of DDT from airplanes.

Preventive measures also played a large part in cutting down casualties in the Air Force. As air surgeon of the Eighth Air Force, Brigadier General Malcolm C. Grow worked out a system of rest camps, the spacing of missions farther apart and the establishment of a definite number of missions that when completed would end the flier's tour of duty in that theater. These antifatigue measures proved highly effective in combating this problem among fliers.

To be certain that aviators had sufficient oxygen they were given courses of instruction in handling personal equipment, and "personal officers" were appointed to see that all missions were started with equipment in proper order. Heaters were developed to cut down the freezing of oxygen masks. These same officers checked clothing and equipment to guard against frostbite and instructed fliers how to prevent it. Engineers were instructed to keep the waist windows in the fuselage closed.

The field of medicine has also proved rich in results in this war. The death rate from disease was only 0.6 per 1000 men per year, as against 16.5 in the last war. The pneumonia rate was cut from 24 in the last war to 0.6, and that of meningitis was lowered from 38 to 4. Days lost due to venereal disease amounted to 47 per case in 1937, whereas last year the days lost per case totaled only 5.

Great advances were made in the adaptation of civilian to military surgery in this war, and improvements in both will be noted in the future from the facts that were learned. A great deal is owed to Colonel E. D. Churchill, surgical consultant in the Mediterranean Theater, for his development and standardization of wound management and resuscitation.

Surgical care has been divided into three echelons. The initial or primary echelon is in forward hospitals, where the wound is thoroughly debrided, left open, immobilized by plaster or splints and made ready for transportation to fixed hospitals in the rear. Resuscitation is necessary at this echelon of treatment. Most of these patients are in shock, and many have lost much blood. Plasma prevented

the Philippines, were studied at an Army general hospital in the United States

Recurrent epigastric cramps and tenderness were the most frequent complaints on admission, but in almost all cases these had disappeared by the time of discharge

Repeated stool examinations by more than one method were necessary to demonstrate the eggs of *Schistosoma japonicum*. A persistent eosinophilia was suggestive but not diagnostic of continued activity of the disease

On the basis of comparable series, treatment with tartar emetic was found to be much more effective than that with fuadin. Significant toxic reactions with tartar emetic were rare

It is urged that stool examinations be done repeatedly and by multiple methods on men who have

been exposed to this disease so that treatment may be instituted if ova are found

WARTIME ACTIVITIES OF THE ARMY MEDICAL DEPARTMENT*

MAJOR GENERAL NORMAN T. KIRK†

IT IS a distinct privilege to be present at this annual meeting of the Tufts Medical Alumni Association. I look back with pleasant memories to about a year ago when I was present at the commissioning exercises of the graduating class of Tufts College Medical School and also those of Harvard and Boston universities. I thoroughly enjoyed renewing old acquaintances and making new friends on that occasion, and I am happy to be with you again tonight.

I am aware of the great contribution that the Tufts Medical Alumni Association and the Tufts College Medical School have made in this war. Some of you may not realize just how close my contact is with your institutions. The office on my immediate left is occupied by the deputy surgeon general, who is Brigadier General Raymond W. Bliss, a Tufts alumnus of the Class of 1910, and the office on my immediate right is that of the executive officer, Colonel Robert J. Carpenter, a Tufts alumnus of the Class of 1914. With an enthusiastic and loyal Tufts alumnus on either side, I think you can understand how I happen to be fairly well informed on your activities.

Tufts College Medical School has a rich heritage, dating back for over half a century, of providing New England and other sections of the country with high-type general practitioners. You have followed a policy of keeping in close touch with your alumni to see that they have kept abreast of modern practices. You have not overlooked the specialties, of course, but you have particularly stressed a program of developing to the highest professional

standards your training of the general practitioner. In this day of specialization I am glad to see that your institution has not overlooked the fact that there is still a definite need for general practitioners in the rural sections.

I realize that everyone in this audience has played an important part in recent years, whether he served in uniform or remained to do the vitally necessary tasks in civilian practice or as part of the staff of Tufts College Medical School. You have contributed more than your share, and I think that you will be interested in hearing something of the overall story of the Army Medical Department's activities in the war. Now that it is over, I can give you a more intimate glimpse into what was done by this department since the start of the emergency.

You know that we had to start practically from scratch. In the Regular Army there were only about 1200 medical officers. In planning an organization geared to the medical needs of an army of 8,000,000, you can see what they meant. Largely because of the foresight and loyalty of professional men of your type, we had a reserve that helped us bring the strength of the Medical Corps to approximately 47,000 at the peak of the war. In addition, there were 15,000 officers in the Dental Corps, 2000 in the Veterinary Corps, 2000 in the Sanitary Corps, 61 in the Pharmacy Corps and 18,700 in the Medical Administrative Corps. The total number of nurses reached approximately 57,000, and there were 535,000 enlisted men trained as medical-aid men, technicians, litter bearers, ambulance drivers, clerks and so forth. The entire Medical Department had to be expanded from a skeleton organization into a full-blown medical machine, which did the biggest job ever performed by American medicine.

*An address delivered at the annual meeting of Tufts Medical Alumni Association, Boston, April 10, 1946.

†Surgeon General, United States Army.

that our task has been finished On March 1, 1946, there were 129,000 patients in Army hospitals, 60,000 of these being evacuees from overseas You can see that we still have a sizable job on our hands In addition, the Medical Department must lay its plans for the interim and postwar care of the Nation's soldiers One important phase of this will be to secure a sufficient number of specialists for the Regular Army and Reserve Corps

Here is where your organization can continue to help in the same grand way that you have in the past Tufts Medical Alumni Association and Tufts

College Medical School will continue to merit the deep appreciation of the Medical Department by giving their full support to the building of a strong Medical Reserve Corps On behalf of the Army Medical Department, I express our sincere gratitude for what you have done, and judging by your members whom I know and the record of your past performances, I am certain that we can count on your unswerving and loyal support in our future plans for the type of Medical Reserve Corps that this country should and must have

SCURVY*

A Survey of Two Hundred and Forty-One Cases

IHSAN DOGRAMACI, M D †

ST LOUIS, MISSOURI

SCURVY is still a reasonably frequent disease in pediatric practice This is a disquieting fact that should cause concern to all responsible for the

At least 241 clinically typical cases of scurvy were seen in these hospitals during the last ten years, according to the lists of the Record Library The cases

FIGURE 1 Morbidity of Scurvy from 1936 to 1945

health of infants, inasmuch as the disease can so easily and effectively be prevented The purpose of this report is to place on record the large number of cases seen in the Infants' and Children's hospitals during the last decade, to analyze the causes of inadequate intake of ascorbic acid and to suggest measures possibly leading to a decrease of the incidence of scurvy

with insufficient data were not included in this report

The criteria used in selecting the cases were two-fold First, all the selected cases had a history of inadequate vitamin C intake or some of the symptoms and signs characteristic of the disease, listed in Tables 1 and 2 Second, the diagnosis was verified in each case by roentgenograms and in a few cases by laboratory measurements or by the rapid therapeutic effect of vitamin C The roentgen-ray evidence of the changes in the long bones included some

†Fellow in pediatrics, Washington University formerly fellow in pediatrics Infants and Children's hospitals

the loss of many lives after injury and previous to arrival at a hospital for surgery. It was soon demonstrated that plasma alone was not sufficient to permit life-saving surgery and must be supplemented by whole blood.

In the second echelon, intermediate or reparative surgery is carried on at the fixed hospital in the rear. Here, plaster and splints are removed, secondary closure is accomplished by plastic procedures or by skin grafts, and fractures of long bones are placed in suspension traction until consolidated and then fixed in plaster for transportation to the Zone of the Interior. Soft-tissue wounds heal much earlier under these procedures, and the soldier is returned to duty in the theater in a much shorter period of time. Compound fractures are converted into simple fractures, and the patients arrive home without osteomyelitis and with advanced union. Patients with colostomies that were performed as a life-saving measure when initial surgery was done are prepared for evacuation to the Zone of the Interior or the colostomy is closed in the theater. Thoracotomy for the removal of blood clot or foreign bodies becomes routine, and many of these patients return to duty in the theater instead of returning home with a drainage tube in the chest, with chronic empyema and marked loss of weight, and requiring extended hospitalization. Penicillin and sulfonamides aid materially in the prevention and control of infection, but they are adjuncts only to good surgery.

The third echelon is definitive or reconstructive surgery—mainly practiced in the Zone of the Interior and at times in the Zone of Communications. Here plastic procedures on skin, nerve, bone and vessels and other procedures are carried on to correct the defect, mobilize joints and prepare the patient for return to the Army or to civil life.

Surgery was an important factor in the following results, which will be of interest to you. Of 598,000 soldiers wounded in this war, approximately 96 per cent who reached Army hospitals lived, 26,600 dying of wounds, 376,000 were returned to duty in the theater, and an additional 55,200 were returned to duty in the United States. One hundred and ten thousand were returned to civilian life with a certificate of disability discharge. There are approximately 30,200 of these patients still receiving treatment in general hospitals here at home. These sick and wounded soldiers received the best medical care as a result of the system of specialized centers that the Army established in general hospitals. There were not enough specialists, so the Army brought the patients to the specialists. The following centers were established for specialized care: seven amputation centers, nineteen neurosurgery centers, five thoracic-surgery centers, eight plastic-surgery centers, two ophthalmologic-surgery and blind centers, three deaf centers, nine deep x-ray-therapy centers, three radium-therapy centers, three vascular centers, nineteen neurology centers,

two arthritis centers, seven centers for syphilis of the central nervous system, two tuberculosis centers, two rheumatic-fever centers and two tropical-disease centers.

An example of how this specialized-center system worked out is afforded in the treatment of paraplegic patients. They are small in numbers,—only about 1400 in all—but the Army has devoted the same amount of effort to helping them as in the case of patients in larger groups. In fact, the results in these cases have surpassed anything in the previous history of neurosurgery and constitute a tribute to the professional competence of the Army doctors in this war. Until this program was instituted, men with spinal-cord injuries and resulting paralysis were regarded as hopeless invalids and, I fear, were treated as such. This attitude has been completely reversed by the Army Medical Corps, which met the problem with all the resources of the profession.

Prompt and skilled surgery was the first step in the treatment of these cases. Nutritionists and dietitians helped to restore underweight patients, who were evacuated to one of the nineteen neurosurgical centers. The next phase of treatment was largely urologic, and a urologist was in constant attendance. Decubitus ulcers were closed by surgery, either by skin grafting or by plastic procedures. Finally came the matter of ambulation. We did not deceive ourselves about this. Ambulation as you and I understand the term is beyond the capacity of all but the incomplete paraplegic patients, but ambulation in the sense of getting about with the aid of braces and crutches sufficiently well to care for oneself is a definite possibility in most patients with cord lesions at or below the tenth dorsal vertebra and is a more guarded possibility in cases with lesions below the second dorsal vertebra. In patients with lesions above this level ambulation is not possible, but a wheel-chair existence is. In other words, so far as this program was concerned, a bed-ridden patient was simply not conceived of. When a man reached a paraplegic center it was taken for granted that he would be out of bed promptly or at least as soon as certain physical deficiencies had been corrected and that he would attempt to walk with equal promptness. An unexplained improvement always occurs when these patients begin to move about. The surprising results we have realized in a majority of the cases have been against untold odds through the untiring and united efforts of neurosurgeons, plastic surgeons, orthopedic surgeons, urologists, internists, nutritionists, nurses, dietitians, physical therapists and hospital corpsmen. These results reflect the value of the specialized centers.

* * *

Most of what I have said refers to the work during the war, but I do not want to leave the impression

blood was present in the stools of 6 patients, whereas in the remaining 2 cases it could be detected only by the guaiac test. Gross hematuria was observed in 1 case, and microscopic hematuria in 3 cases.

The temperature was elevated in 40 per cent of the 228 cases in which it was recorded. In 65 per cent of all febrile cases no associated infection could

TABLE 2 Physical Signs on First Physical Examination (241 cases)

be demonstrated, the fever apparently being related to the scurvy. An increased susceptibility of scorbutic patients to infection³ was confirmed in this survey. Thirty patients (12 per cent) had concurrent infections of the upper part of the respiratory tract. This means that the incidence of infection of the upper part of the respiratory tract was at least five times as high in the patients with scurvy as in the total number of all patients admitted to the Outpatient Department over the same period of time. Thirty-one patients (13 per cent) had miliaria, and an equal number had amoniacal dermatitis. The incidence of rickets was high, this symptom appearing in 22 patients (9 per cent). Anemia was also a relatively frequent finding, 12 per cent of all patients having an appreciable degree of anemia, usually of the hypochromic type. Six patients (2 per cent) had had pertussis at some time before the onset of scorbutic symptoms. Five patients (2 per cent) had definite signs of pneumonia when admitted to the hospital, in addition to frank evidence of scurvy.

The following case was particularly interesting in that scurvy simulated pneumonia.

R S, a 7-month-old boy, was admitted because of a generalized rash and crying for the 3 weeks prior to entry. He had not been receiving adequate amounts of vitamin C. Shortly before entry the gums became swollen and developed purplish areas anteriorly.

Physical examination revealed a well developed and well nourished pale, slightly cyanotic infant lying apathetically, with the legs held in the so-called "frog's leg" position and the right arm outstretched. The temperature was 101°F. The respirations were rapid, shallow and slightly irregular, with occasional cough. A macular rash was present over the anterior thorax, abdomen and lower legs, some of the lesions had brownish crusts, and many were petechial. Both eardrums were full and injected. The upper and lower gums were swollen, spongy and livid, with small petechial hemor-

rhages visible anteriorly. The pharynx and tonsils were reddened. The lungs contained a few scattered rhonchi. The legs were swollen and tender, and there was considerable beading of the costochondral junctions. The hemoglobin was 49 per cent, the red-cell count 3,460,000, and the white-cell count 15,700, with 75 per cent neutrophils. Blood Wassermann and tuberculin tests were negative, a throat culture was noncontributory, and urine examination was within normal limits. The plasma ascorbic acid level was zero. Roentgen-ray examination of the long bones showed advanced active scurvy.

It was thought that in addition to scurvy the patient had pneumonia, and he was placed in an oxygen tent. Because of the moderate anemia and the patient's acutely ill appearance, blood was transfused the day after entry. In spite of the giving of oxygen, the respirations continued to be rapid and the cyanosis persisted. Roentgenograms showed no evidence of pneumonia, and it was thought that the respiratory difficulty might be a manifestation of the so-called "cardiorespiratory symptom of scurvy" and he exaggerated by excessive pain and tenderness of the ribs. Accordingly, morphine was given in regularly repeated doses. This resulted in prompt relief, including disappearance of the cyanosis.

From 4 to 8 ounces of orange juice was administered daily. No chemotherapy was instituted. The rhinitis persisted and the inflammatory process in the ears did not subside. Paracentesis was done in the 4th week, with release of pus from the right middle ear and the patient was discharged free from symptoms 32 days after entry. During the last week, the temperature remained normal. Roentgenograms of the long bones taken shortly before discharge showed signs of healing scurvy.

ROENTGEN-RAY FINDINGS

In 127 of 133 cases examined roentgenologically, bone changes characteristic of scurvy were found. In 4 cases the changes were minimal but suggestive, whereas in the remaining 2 cases the findings were equivocal.

LABORATORY DATA

In 24 cases fasting plasma vitamin C levels were determined (Fig 4), and a mean value of 0.087 mg of ascorbic acid per 100 cc with a range of 0.0 to 0.3 mg was found. The mean value for normal infants with adequate nutrition is between 0.8 and 1.4 mg.⁴ Although low plasma vitamin C concentration value is a constant finding in untreated scurvy, it is by no means a certain indication of vitamin C depletion.⁵ Butler and Cushman's⁴ method of analysis of the whole blood and the white cells and platelets is recommended to obtain a more reliable index of vitamin C deficiency.

In 7 patients showing low values of ascorbic acid in the plasma and its absence in the urine, large doses of crystalline ascorbic acid were administered over several days, and vitamin replenishment was accomplished quickly or over a longer period of time, depending primarily on the dose of ascorbic acid employed.*

The serum alkaline-phosphatase level was measured in 26 scorbutic patients, and the results were found to be abnormally low. In 1 patient the phosphatase value was 0.19 Kay units (the value for a normal infant of the same age is 0.26 Kay units⁷). The average value in the remaining 25 cases† was

*The details of this study have been reported by Ingalls.⁶

†The results of 18 cases in this series have been published in detail by Schwachman.⁸

or all of the following signs Park's so-called "corner sign," cortical atrophy, ground-glass atrophy of the ends of the shaft, Fraenkel's so-called "white line" and in many cases evidence of swelling of the soft tissues of the lower extremities

The incidence in males and females was approximately the same (Fig 1)

The seasonal distribution is rather irregular in scurvy It is sometimes said to be most frequent in winter and spring¹ Park² observed that the greatest number of cases occur in September and October

FIGURE 2 Seasonal Incidence of Appearance of the First Symptom of Scurvy (241 cases)

In the present series the incidence was high during the summer months and low in October, November and December (Fig 2)

From Figure 3 it is clear that in the majority of the cases the first symptoms appear between the ages of five and eleven months

SYMPTOMS AND SIGNS

The earliest symptoms noted are arranged in Table 1. Tenderness of the extremities was by far the most frequent complaint, and the lower extremities were affected thirty-nine times as frequently as the upper. In 15 patients the tenderness had allegedly followed some minor trauma. In 6 cases scurvy was discovered in the course of a

routine physical examination in the hospital, and in 1 case the typical roentgen-ray finding was the first noted sign, it was discovered when the patient

FIGURE 3 Age Distribution at the Onset of the First Symptom of Scurvy (241 cases)

The columns represent the percentage incidence in each month of age

was referred to the Department of Roentgenology for some other complaint

The principal physical findings attributable to scurvy noted at the time of the first examination are

Symptom or Sign	No. of Cases	Percentage
Tenderness in one or both lower or upper extremities	161	67
Irritability and generalized tenderness†	59	24
Anorexia and failure to gain weight	22	9
Diarrhea or vomiting or both	15	6
Involvement of gums	15	6
Skin rash	3	1
Blood in stool	2	—
Blood in urine	1	—
No specific complaint (scurvy discovered in hospital)	7	3

*In several cases the history contained more than one early symptom, the most frequent combination being irritability and tenderness of one or both lower extremities. This accounts for the fact that the total number of first symptoms exceeds the total number of patients.

†Irritability was present in the history of 107 patients (44 per cent), but it was the earliest symptom in only 59 cases.

listed in Table 2. Tenderness in the lower extremities was eleven times more frequent than that in the upper, and swollen lower limbs were observed five times as frequently as swollen upper limbs. Gross

28 per cent, ascorbic acid in 66 per cent and both in 6 per cent

* * *

In view of the increasing efforts toward the provision for better health and the supposedly widespread dissemination of nutritional information among present-day mothers, it is surprising that one hospital should have received such a large number of definite cases of scurvy in the last ten years. The incidence in this decade was 41 cases of scurvy per 100,000 outpatient visits, as compared with an incidence of 58 cases during the previous decade. Figure 1 illustrates the steady decrease until 1940, following which a rise occurred during the next five years. The shortage of citrus fruits and their higher cost during the war years may account for this rise. The relative unavailability of physicians during the war years may have been an additional factor.

There is little doubt that mothers of scorbutic children are familiar with the idea of the necessity of vitamin C in the children's diets. The demonstrated frequency of this preventable disease, however, indicates that far more emphasis must be laid on this point in the community. Special stress should be put on the danger of the false sense of security that exists during the rather long latent period between beginning of the deficiency in diet and the onset of symptoms. The following measures are suggested in an attempt to reduce or abolish scurvy in modern communities. First, mothers

should be educated by obstetricians and pediatricians concerning the vital need of regular administration of vitamin C in adequate amounts to infants. Second, every physician should question the mother routinely concerning vitamin C intake whenever a child is seen. It is of interest in this regard that extremely few of the babies in this series had not been seen by a physician for some reason before the onset of symptoms. Hence, the fact that the intake of vitamin C was inadequate could have been determined and measures could have been taken to correct the deficiency. Lastly, the public should be educated to accept the cheaper ascorbic acid as a substitute for citrus fruits, whenever the use of the latter is not feasible.

FACTORS LEADING TO AN INADEQUATE VITAMIN C INTAKE

Some explanation of the reasons for inadequate intake of ascorbic acid was given in the records of

In still another case, a physician had allegedly remarked that the canned foods for babies contained enough ascorbic acid and that additional vitamin C was not necessary. In many cases, the mother claimed that she had been faithfully offering the infant sufficient amounts of orange juice, but further inquiry revealed that in most of them the infant constantly refused it. In 7 cases, however, the informant continued to insist that the child had been

172 cases (Table 3). In 51 cases, orange juice was omitted because of a rash or gastrointestinal disturbances believed to be ascribable to it, without substituting vitamin C in some other form. In 28

receiving adequate quantities of orange juice or ascorbic acid.

All these cases revealed roentgenologic findings characteristic of scurvy. In all, the daily administration of 150 to 200 mg. of ascorbic acid rapidly relieved the patients of their symptoms. The alleged vitamin C intake is summarized in Table 4.

EFFECT OF TREATMENT

The effect of treatment was recorded in 124 cases. Most of the remaining patients were referred to

TABLE 4 Data Concerning 7 Patients Who Were Allegedly Receiving Sufficient Quantities of Vitamin C

AGE mo	VITAMIN C INTAKE ACCORDING TO HISTORY
8	2 oz. of orange juice daily, not boiled
6	3 oz. of fresh orange juice daily, not boiled and no soda added.
10	3 oz. of fresh orange juice daily, all retained
6	2-3 oz. of orange juice daily
11	25 mg. of ascorbic acid daily
7	3 oz. of orange juice daily
6	2 tablets of ascorbic acid daily during the previous 3 mo

cases, orange juice was boiled or heated or mixed with hot or boiling water. In 1 case, the mother claimed that administration of vitamin C was not recommended while the formula was prescribed

their own physicians after a diagnosis had been made and vitamin C therapy had been instituted. Relief of symptoms took place rapidly in all the observed cases. Orange juice was administered in

in each case being determined both by the patient's clinical condition and by a modicum of regard for his comfort, the total period of withdrawal, however, not being permitted to exceed three hospital days or to include more than a certain maximum of alcohol

The regimen may be summarized as follows. The diet is of high-calorie, high-vitamin type. Fluids are forced, with special emphasis on fruit juices. Liberal supplementary vitamin B₁ is given orally in all cases and intramuscularly or intravenously in those showing signs of vitamin B₁ deficiency — tremors, excessive sweating or any trace of confusion or disorientation — or giving a history of grossly inadequate recent dietary habits. Further medications include some form of antacid for control of gastric and systemic acidity and biters before each meal as a stimulant to appetite. Physiotherapy and hydrotherapy are included in the daily schedule, together with occupational therapy in graduated amounts. Psychotherapy is given so far as possible, although necessarily in only preliminary and superficial fashion during the actual withdrawal procedure. During the daytime hours, a mixture containing 0.67 gm of chloral hydrate and 2.0 gm of bromide compound is given as necessary for restlessness, but not oftener than once in four hours. At night, either 0.1 to 0.3 gm of pentobarbital sodium or 8 to 20 cc of paraldehyde is used as a hypnagogue. Whisky is used as the source of alcohol during the reduction period, in doses of 30 cc, not exceeding a maximum allowance of 240 cc during the first hospital day, 180 cc during the second and 120 cc during the third. In this study, the control cases were treated by the above regimen.

The cases in the insulin series differed in their treatment only in the addition of 10 units of insulin subcutaneously twenty minutes before meals two or three times daily and the fortification of the milk or fruit-juice interfeedings with 4 gm of cane sugar.

During the course of the study the subjective comfort of the patients receiving insulin was so definitely increased that it was believed that the usual supplementary sedation could be drastically reduced, and in the later patients of the series, 10 gm of bromide compound or 15 mg of phenobarbital, to a maximum of every four hours, was substituted for the mixture containing chloral hydrate and bromide compound. The significance of this will be referred to in more detail later.

In keeping with the previously mentioned policy of using gradual reduction of alcohol, no attempt was made in this series to withhold alcohol except as in line with the restrictions described heretofore. In a few cases the procedure was to stop whisky abruptly and institute subcutaneous insulin and intravenous glucose in the standard fashion. Patients with delirium tremens, confusion or other states of extreme toxicity, as well as those with

marked malnutrition, debilitation, vomiting or intercurrent infection, were likewise treated by abrupt withdrawal of alcohol and use of insulin and glucose. None of the patients who received the combined insulin-glucose therapy are included in this study, either as cases or as controls.

RESULTS

Duration of Withdrawal Period

The comparative durations of the withdrawal period in the 43 insulin-treated cases and in a control series of 564 patients who did not receive insulin were computed. Since the patient is inclined to judge the progress of his withdrawal by days much more than by hours or total amounts of alcohol and to adjust his demands in accord with this concept, comparison of length of withdrawal in terms of hospital days during which whisky was administered was considered to be the best standard of comparison between insulin cases and controls. With the same standard of computation applied to each, the durations may be compared with validity. On this basis, the cases receiving insulin received alcohol for slightly less than half the period required by the control cases, the average duration of the withdrawal periods being 10 day and 22 days, respectively.

Of equal significance are the comparative figures concerning the number of patients in the two groups who required no whisky subsequent to admission and in whom withdrawal was immediate. Forty-four per cent of the insulin patients received no alcohol whatsoever, as compared with only 14 per cent of the control group.

Ease of Withdrawal

It is obviously impossible to evaluate ease and comfort of withdrawal statistically. It was apparent, however, to both nursing and medical staffs that patients receiving insulin were on the whole more contented and co-operative, less restless and fault-finding and less insistent in their demands for alcohol than were the control patients. This, of course, is borne out by the figures given in the preceding section, since in all the cases, as previously explained, the reduction of the withdrawal period below the three-day limit was more dependent on the patient's comfort and co-operation than on dictum or compulsion. Not infrequently, patients who had formerly been deprived of alcohol without insulin commented on their greater comfort, both physically and emotionally, under the insulin treatment.

Requirement of Sedation

It was observed that with the decrease in restlessness and discomfort under insulin treatment, an appreciably less amount of supplementary sedation was required. As previously mentioned, this was

THE TONIC EFFECTS OF INSULIN IN ACUTE ALCOHOLISM*

ETEM G VASSAF, M D,† AND VOLTA R HALL, M D ‡

ARLINGTON, MASSACHUSETTS

IN all toxic states, the prompt removal of the toxic agent must be the prime consideration in therapy, with the counteracting of its toxic effects and the restoration of impaired organs and their functions as secondary although vital factors. In the treatment of acute alcoholism, rapid elimination of alcohol is important, not only from the point of view of the patient's physical well-being but also for the psychologic implications, in getting him as quickly as possible through the difficult period in which he has not enough alcohol to render him emotionally analgesic, yet too much to permit clear intellectual functioning and satisfactory co-operation. Accordingly, the consideration of means of prompt elimination of alcohol in acute alcoholism has been the subject of much investigation. Attention has focused on the roles of insulin and of glucose, both singly and in combination, on the rate of alcohol oxidation and detoxification.

Chronologically, the consideration of the effects of glucose on the oxidation and detoxification of alcohol preceded that of those of insulin. The difference in effect of alcohol when taken on a full or on an empty stomach has been known to the laity for many years. It was at first assumed that the ingestion of food previous to or simultaneously with that of alcohol reduced the effect of the latter by slowing its absorption. Investigation has shown, however, that the effect is a much more specific one. Thus, Mellanby¹ and later Southgate² and others showed that food taken with alcohol reduces the level of blood alcohol, in line with this it was demonstrated that the toxicity of alcohol is in inverse ratio to the blood sugar level.³ These observations were confirmed and explained by studies showing that glucose speeds the oxidation of alcohol both *in vitro*⁴ and *in vivo*.^{5,6}

With the established intimate relation of insulin to glucose metabolism, it was inevitable that attention should also be given to the effect of insulin on the oxidation and detoxification of alcohol. Results of these studies have shown considerable variance through a voluminous literature, an excellent bibliography of which is given by Clark, Morrissey, Fazekas and Welch.⁷ The evidence for the efficacy of insulin, however, is too great to be ignored, and the preponderance of evidence has been on the positive side.^{7,8}

Clinically, the tendency has been to use insulin and glucose in combination in speeding the elimina-

tion of alcohol. The beneficial clinical results of this form of medication have been incontrovertibly established. This technic was naturally first applied in cases of pathologic intoxication and other acute alcohol toxicities such as delirium tremens and alcoholic hallucinosis. At present it is established as the recognized treatment for this group of disorders.⁹ It has, also quite naturally, been extended to use in the milder, relatively uncomplicated cases of acute alcoholic intoxication, in which it has again shown excellent clinical results.¹⁰

In all this use, the insulin has usually been considered as a secondary factor that acts indirectly by furthering the metabolism of the glucose, which is primarily responsible for the more rapid oxidation of the alcohol, so that, as has been said, "the alcohol burns in the flame of carbohydrate," much as does fat in the treatment of diabetes mellitus. Thus, in the treatment of the more grossly toxic alcoholic states, glucose is given intravenously soon after the insulin, and supplementary carbohydrate by mouth is given subsequently. The same procedure has been used in the simpler states of alcoholic intoxications. Wortis, Bowman and Goldfarb¹⁰ and others, however, have used oral glucose alone in these cases, with equally good results. It has been emphasized, however, that liberal covering of the insulin by glucose is essential and that insulin reactions must be carefully watched for.

It is the purpose of this paper to present the findings in a series of patients with uncomplicated alcoholic intoxication who were treated by being given small doses of insulin, but who were not given the usual coincident liberal amounts of glucose as such.

MATERIAL

The material consisted of 43 patients admitted for acute alcoholic intoxication, of whom 29 were men and 14 women. The duration of the acute alcoholic episode varied from two days to three months. The cases were taken at random and unselected from the group of regular admissions. It may be mentioned that, in comparison with alcoholic patients as a group, all our patients, both those included in this study and those in the control group, were in general in the higher economic and social levels.

METHOD

For some time the customary withdrawal procedure for uncomplicated cases of acute alcoholic intoxication in this hospital has been one of gradual reduction of alcohol, the actual rate of withdrawal

*From the Ring Sanatorium and Hospital, Arlington.

§Medical director, Ring Sanatorium and Hospital.

also indirectly with the metabolism of proteins and fats, particularly the latter^{6 13} Thus, re-establishment of normal glucose metabolism also reduces the toxic effects of the intermediate metabolic products of these classes of foodstuffs

SUMMARY AND CONCLUSIONS

A series of 43 patients admitted for acute alcoholism were treated by gradual withdrawal of alcohol, with the addition to the control regimen of small doses (10 units) of insulin two or three times daily before meals, without coverage by glucose as such

The insulin-treated cases as compared with the control group showed the following clinical differences The average speed of the withdrawal period was twice as great Three times as many patients neither required nor demanded any whisky after admission Subjective ease and comfort during the withdrawal period were increased The requirement of supplementary sedation was greatly reduced, in some cases to zero The weight gain was increased by threefold, both during the first week of hospitalization and subsequently

Insulin reactions were rare and mild, being readily controlled by oral sugar

The coverage of clinically effective doses of insulin by glucose as such is apparently not a vital clinical necessity

The use of insulin in small doses deserves serious consideration in the treatment of acute alcoholism

MEDICAL PROGRESS

DISEASES OF THE VEINS (Concluded)

JOHN HOMANS, M D *

BOSTON

Anticoagulant Treatment

The anticoagulants, represented by heparin and dicumarol, have been extensively used in many large clinics, particularly by way of postoperative prophylaxis against thrombosis and embolism The most significant recent figures come from Swedish sources and from the Circulatory Division of the Mayo Clinic

As a background for the latest Swedish figures, the second report of Crafoord²⁸ from Stockholm may be recalled Heparin was given prophylactically in surgical cases The earlier method of continuous intravenous drip had been abandoned The drug was given routinely in four intravenous doses of something like 75 mg three times during the day, and in a dose of 125 mg to carry the patient through the night A series of 325 postoperative cases, in all of which the patients were over forty years of age, was compared with 302 control cases, not heparinized Among the latter were 33 cases of thrombosis and

embolism (11 per cent) Among the heparinized patients no thrombosis or embolism was observed, but there were 3 cases of unexplained fever, suggestive of thrombosis Outside these series, 40 cases of established thrombosis were treated by heparin, usually with excellent results, but 1 patient actually developed thrombosis and fatal embolism under heparin and died

Bauer has used a closely similar system of heparin administration, although only for recognized thrombosis The account of his²⁹ observations at the Manestad Hospital, covering the five-year period from October, 1940, to October, 1945, is illuminating No prophylactic treatment was used, but the staff watched for the earliest local and general signs of thrombosis in the lower leg, believing that 95 per cent of all such processes start in the deep (fibular) veins of the calf Suggestive signs called for phlebography If this was negative, no action was taken If it was positive, 150 mg of heparin was given intravenously and one or two more doses of the same size were given on the same day at intervals of four

*Surgeon emeritus Peter Bent Brigham Hospital

observed during the course of the study, and the amount of sedative was drastically decreased and in several cases was reduced to zero. The patients treated with a minimum of sedation or none at all did fully as well, however, as did those given the larger amounts. Thus the average period of whisky requirement was 0.9 day in the former and 1.1 days in the latter, whereas it was 2.2 days in the controls. In other words, the speed of withdrawal in both groups was essentially twice that of the controls.

Nutrition and Weight

The comparative average gain in weight during successive weeks of hospitalization was calculated for the 43 insulin-treated cases and for 40 control cases. During the first week, which included the actual withdrawal period, patients treated with insulin gained on an average of 2.0 pounds, as compared with 0.6 pound in the controls. During the second week, the average gains in weight were 1.9 pounds in the insulin cases and 0.5 pound in the controls. During the third week, the average weight gains were 1.1 pounds and 0.4 pound, respectively. Both the insulin-treated patients and the controls were served the same diet, although no patients were forcibly fed on the one hand or refused second servings on the other.

Circulatory Changes

Recordings were made of blood pressures and pulse rates as readily determinable indications of circulatory function. The findings in regard to blood pressure showed no consistent trends. Thus, approximately equal portions of the two groups showed a rise of blood pressure above the admission level by the end of the first week of hospitalization, a fall below the admission level and no appreciable change in blood pressure — that is, difference of less than 5 mm diastolic and 10 mm systolic. In general the changes, when they were appreciable, showed approach toward more normal levels. Pulses were characteristically found to be rapid, full and bounding on admission, with a later fall in rate and improvement in quality.

There was no appreciable difference in the two groups.

Insulin Reactions

Among the 43 cases, there were only 3 cases of insulin reaction at a clinical level. Two of these occurred within one hour of the insulin injection, and the third occurred after a lapse of four hours. All the reactions were extremely mild, being characterized by slight perspiration and a feeling of weakness, without changes in pulse rate or blood pressure. They were readily controlled by the administration of 250 cc of orange juice fortified with 20 gm of cane sugar. In no case was it necessary to have recourse to intravenous glucose, which, however, was always available.

COMMENT

The findings described above are of significance not only as demonstrating clinically the effectiveness of the administration of insulin without glucose but also as perhaps shedding some further light on the whole matter of the relation of insulin and glucose to alcohol oxidation. Interpretation of these findings may take one of two main lines.

On the one hand, it may be assumed that the good clinical results are due not to any direct effect of insulin but rather to the effect of glucose already present in the body or derived from the subsequent meal but mobilized by the insulin given. To be sure, the dosage of insulin in this series was relatively small (10 units) and could be covered without too much difficulty by the glucose deriving from the carbohydrate of the subsequent meal. Yet the clinical results demonstrate that whatever amount of insulin was given was of significance. At the same time, the infrequency and mildness of insulin reactions in these cases indicate that the amount of glucose available must be not inconsiderable. Of course, there are the glycogen stores of the liver and muscles, but these are likely to be more or less depleted in the alcoholic patient, and one would hesitate to deplete them further. It appears, however, that dipping into these stores may not be essential to cover any deficit in the food. It has been observed that alcoholic patients show reduced sugar tolerance and high blood-sugar curves, with ready propensity to hyperglycemia and glycosuria.¹¹ This may be due to the fact that when alcohol and glucose are simultaneously present in the blood, the alcohol tends to be oxidized in preference to glucose.¹² Furthermore, with the usual deficiency of carbohydrate in the diet of the average alcoholic patient, there is a lessening of the usual stimulus for endogenous insulin production, so that for this reason also glucose oxidation is impaired. By the administration of insulin, therefore, as in this series, the metabolism of this otherwise impotent glucose is furthered, and there is a breaking up of the vicious circle in which alcohol directly or indirectly interferes with the metabolism of the element — that is, glucose — that would in turn otherwise speed the elimination of the alcohol itself.

On the other hand, Clark, Morrissey, Fazekas and Welch⁷ have shown by experimentation with animal tissues both *in vitro* and *in vivo* that in the initial oxidation of alcohol by the liver insulin is in itself an essential factor, apart from glucose. Accordingly, the administration of insulin alone, as in this series, would be of direct significance in the oxidation of the alcohol present without necessarily being entirely dependent on glucose metabolism.

In considering the clinical picture of acute alcoholism and the clinical results of insulin treatment, it must also be borne in mind that alcohol interferes not only with the metabolism of carbohydrate but

tolerance test and the thromboembolic problem in general

Thrombosis following leg injuries has been serious enough to call for special treatment by both operative and chemical methods. Allen Linton and Donaldson⁷ speak briefly of prophylactic vein ligation in fractures of the hip. Golodner, Morse and Anguist⁸ found that among 86 fatalities in 504 cases of fractured hip 25 autopsies revealed 9 cases of pulmonary embolism. There may, of course, have been many more, but in any case pulmonary embolism was the most frequent cause of death. These authors recommend prophylactic, bilateral superficial femoral-vein ligation combined with sympathetic lumbar block, especially for patients who cannot be made ambulant early.

Bauer⁹ finds the incidence of thrombosis in leg injuries to be 12 per cent, as compared with 1.6 per cent after surgical operations, 10 per cent after childbirth and 2.1 per cent in medical patients. It occurred almost exclusively in the injured leg. He believes that many cases have gone undiagnosed or at least have not been diagnosed until persistent swelling and pain have called attention to the late stage of the process. Since diagnosis is particularly difficult in the case of fracture, because of plaster casts, splints and other apparatus, he recommends, besides the usual elevation of the foot of the bed and the greatest possible use of the muscles, the routine administration of heparin in the same dosage as in the postoperative group of cases. Under this treatment, he finds a reduction in the mortality from pulmonary embolism in traumatized patients, during three years of trial, to less than one fifth of that previously observed.

Complications of Thrombosis

Bauer's⁹ exhaustive monograph on the sequelae of thrombosis deserves detailed study. It is written with the point in mind that since 97 per cent of all obstructive femoral thromboses start in the lower leg, it is most important that early diagnosis be made and that efficient treatment (by heparin) be given to prevent the process from reaching even the popliteal vein. For once an obstructive thrombophlebitis — phlegmasia alba dolens — has become established one must expect that edema of some degree will follow in 100 per cent of the cases. Moreover, indurations, such as often lead to ulcers, are present in 45 per cent at the end of five years, in 72 per cent at the end of ten years and in 91 per cent after a still longer period. Bauer holds that a deficient venous return is always responsible for the edema, and he ignores both lymphatic and vasoconstrictive elements in the edema problem. One must admit the significance of Bauer's figures without fully agreeing with his explanation of postphlebotic edema and induration.

I myself have been interested for years in the postphlebotic leg and have regarded edema as the

basic change that leads to so much misery and incapacitation. In a paper read before the New England Surgical Society in 1946 and now in process of publication I presented an account of the various late complications as I had encountered them in ambulatory patients outside a hospital clinic (Hospital practice includes an unduly high incidence of ulceration). Edema was very frequent, induration and ulceration were second in importance and there were also found many cases of a mild causalgia-like pain complex of recurrent thrombosis and of venous congestion including varicosities. It did not seem to me that venous stasis was the whole story. There were late effects resulting from the intense peripheral vasoconstrictions of the acute disease, which could be relieved by sympathetic lumbar block or sympathectomy and there were cases in which there was present not only a secondary saphenous varicosity but what might be called femoral varicosity as well.

I¹⁰ had previously presented the view that in some postphlebotic states the recanalized femoral vein might be regarded as the source of stasis and back pressure or even back flow of venous blood. In selected cases the femoral vein might be sectioned with satisfactory results, the leg being afterward less heavy and congested. The explanation seemed to be that since the femoral vein was functionally useless a collateral circulation must necessarily have been established and treatment of the femoral as a varicose vein was therefore entirely logical. In a limited series, these conclusions have proved to be correct, although I cannot see that edema has been favorably influenced by the operation. In some cases I have interrupted the vein at a level higher than the inguinal ligament.

Buxton and Coller,¹¹ who have taken a similar view, make their second report of postphlebotic femoral-vein ligation. Superficial varices have been sectioned along with the deep veins (femoral or common iliac). Ulcers have as a rule been cured, although the authors are not convinced that the good care given their patients has not contributed more than the operation to the favorable result in some cases. Operations done mainly for edema and fatigue have been disappointing.

My comment is that the postphlebotic state deserves more study than it has hitherto received. Possibly as Bauer suggests early restraint of thrombosis by anticoagulants will prevent many of the present-day complications. Once the femoral vein is fully obstructed, surgical attack with thrombectomy may act much like lumbar sympathetic block in doing away with reflex vasoconstriction and its consequences. Should the anticoagulants prove fully as life-saving as operative measures or actually more so, they will probably be preferred as securing a better postphlebotic leg. For in early cases, at least they should leave behind a functioning valved upper and perhaps even lower femoral vein.

hours. Then, three daily doses of 100 to 150 mg each were administered, without any study of the blood. In four or five days the temperature usually returned to normal, local signs in the leg disappeared, and the patient was made ambulatory, after one more day, heparin was withdrawn. The average stay in bed was 4.7 days, and the average total dose of heparin was 1700 mg.

In 209 cases of proved thrombosis so treated there were 3 deaths from embolism, all nonpostoperative, a mortality of 1.4 per cent, as compared with 18 per cent in earlier (control) years. Since heparin was not given until five to seven days after operation, no hemorrhage of consequence occurred. Special advantages of this line of treatment were found to be a greatly shortened convalescence and such a restriction of the thrombotic process that the secondary complications of edema and venous congestion were almost completely absent. The confinement of thrombosis to the lower leg and preservation of the popliteal vein were looked on as decided gains resulting from the treatment, but if phlegmasia alba dolens had developed, the use of heparin, although seemingly effective, did not ward off the late secondary complications.

It will be noted that Bauer does not claim 100 per cent success from this system and makes it clear that its use calls for early and accurate diagnosis. For those who wish to study Bauer's method in detail, his exhaustive paper on the sequels of thrombosis⁹ and his account of thrombosis following leg injuries¹⁰ are also available.

Barker, Cromer, Hurn and Waugh³¹ have published a report on the use of dicumarol in the prevention of postoperative thrombosis and embolism, based on 1000 cases at the Mayo Clinic. They make a special point of dosage and safe administration. The drug was given routinely, and the prothrombin deficiency was estimated by daily blood tests after the method of Quick. They tried for a prothrombin time of thirty-five seconds (bleeding did not occur if the time was under sixty seconds), which corresponds to 20 per cent of prothrombin in the blood plasma. No fatal pulmonary embolism occurred during the one to three days between the first administration and the establishment of the required prothrombin deficiency. Dicumarol was preceded by temporary administration of heparin and the prothrombin deficiency was maintained for several days to a week after the patients had become ambulatory. Actually, the deficiency might continue for two to ten days after administration had ceased, so that daily tests were kept up until normal levels were reached.

Some patients, most of whom had suffered no thrombosis or embolism, were found to be highly sensitive to dicumarol. In such cases the prothrombin level might fall to less than 10 per cent after the first one or two doses. Bleeding was likeliest to occur in this group and required control

by blood transfusion and large intravenous doses of menadione bisulfite (synthetic vitamin K). The doses of dicumarol used were, it seems to me, rather large — 300 mg on the first day, 200 mg on the second day and 200 mg on each succeeding day that the prothrombin in the blood was more than 20 per cent of normal.

The authors hold that even when a thrombus is present, dicumarol will prevent embolism, since old thrombi remain attached to the walls of the veins, and they regard it as the treatment of choice for serious embolism when its source is obscure.

Another instructive account of dicumarol administration comes from Reich, Hahr, Eggers and Lipkin.³² Both prophylactic treatment (102 surgical cases) and treatment of established thrombosis (33 cases) and embolism (9 cases) were employed. These cases arose among 2591 surgical and obstetric experiences. Uniformly favorable results were secured, and no fatalities resulted. The authors question whether routine use of dicumarol is advisable but are convinced that the drug should be given in all cases in which thrombotic complications are likely to arise, including pelvic operations, intra-abdominal cancer and surgical procedures in patients who have shown a previous tendency to thrombosis. Heparin may properly be given, it is stated, during the latent period before dicumarol produces its effect. Tables of dosage are offered.

In choosing an anticoagulant, one should have in mind the promising method of administering heparin devised by Loewe and his associates.³³ These authors have taken up the Pitkin menstruum, a gelatin-dextrose-acetic acid combination, as a means of delivering heparin to the patient over a prolonged period. They have worked out the required dosage and the appropriate intervals, with and without the aid of vasoconstricting drugs. According to their latest report they had treated 125 cases of thromboembolic disease, 42 of which had already suffered pulmonary embolism. Among these 42 cases were 4 fatalities, which are reported in detail. Clinical improvement, as a rule, was striking. Heparinization, these authors believe, must be continued for ten to fourteen days in uncomplicated phlebothrombosis, but when pulmonary infarction has occurred three or four weeks are required. The full heparin effect must still be present when the patient is first allowed out of bed. Lange and Loewe³⁴ record further experience with the method in the treatment of experimental human frostbite. It should be noted that earlier trials with the intramuscular injection of heparin itself, as attempted by Walker,³⁵ had proved that such injections were very painful. Walker also used various menstruums.

De Takats and Fowler,²¹ who have previously been quoted as making use of both operative and chemical methods, give an excellent account of the combined heparin-dicumarol sequence, their heparin-

of cases, he has encountered a minimum of accidents, and reports excellent results

For Sherman's method of injection and stripping, a system of stripping with actual exposure and section of the large branches as they join the varicose saphenous vein in the thigh might well be substituted — a procedure long used by me in former times and recently advocated by Sapiro⁴⁶ It is probable, however, that Sherman's retrograde injection does not offer the same hazard of penetration of strong solutions through direct perforating veins into the deep system, as is incurred when retrograde catheterization and injection down into the veins of the lower leg are employed Lyall⁴⁷ strongly recommends this retrograde injection (after Pratt's plan) although he notes some disturbing post-operative febrile reactions of considerable severity (One may well ask whether some of these reactions are not evidence of a deep thrombophlebitis) Smyth,⁴⁸ who also uses Pratt's retrograde catheterization into the veins of the calf again notes a number of complications, including reactions to the sclerosing agents My own comment on these observations is to question the value of such retrograde injection Probably it ensures a little more thorough severance of all possible varicose connections, but considering its occasional undesirable effects and its failure to obliterate permanently the veins it enters (mere thrombosis does not mean obliteration), I question the advisability of its continued use

It is worthy of note that McPheeters,⁴⁹ the exponent par excellence of the injection treatment of varicose veins, writes in favor of saphenofemoral ligation with immediate retrograde injection, stating that "the theory that the preliminary ligation is the first and perhaps the most essential step in the treatment is based on the now proved fact that the flow of blood in any well developed cases of varicose veins is actually reversed" — a matter that he had a large part in demonstrating He advocates emptying the leg veins by elevating the foot of the table during the operation and, on reversing this position, injecting two thirds of the sclerosing solution into the lower saphenous stump Thus, he believes that he fills all saphenous tributaries down to the foot As complications, he cites occasional severe chemical phlebitis and the associated cellulitis following the injections of too large amounts of the sclerosing solution He has seen cases in which the lower leg and even the thigh were swollen after operation

For an account of a return nearly to the radical dissections of earlier days one should read Hodge, Grimson and Schiebel's⁵⁰ paper on the treatment of varicose veins by stripping, excision and evulsion A review of the older surgery is given The authors treated many difficult cases, including postphlebotic varices and those complicated by ulcer They carried out the usual full dissection in the groin and then removed the varicose veins by stripping and

evulsion down to the ankle, making some lower-leg dissections and undercuttings They applied pressure bandages and used early mobilization In a fairly short series (195 cases) they encountered no pulmonary embolism

I have tried here to show how the treatment of varicose veins has swung more than a full circle Actually, it has gone from injection to Trendelenburg's ligations in the thigh, to radical dissection, including that of the lower leg, then back to injection again, to high ligation plus injection and now to radical dissection The conscientious surgeon should recognize these cycles and draw conclusions accordingly

A freakish sort of varicosity is described by Prioleau⁵¹ as originating from the gluteal vein Such a congenital anomaly is not difficult to identify, but it recalls the hemangiomas, which closely imitate saphenous varicosity The importance of these lesions lies in the danger of dealing with them surgically Immediate and late hemorrhage are serious dangers

The value of venography in the diagnosis and treatment of varicose veins is discussed by Imler, Beaver, and Sheehan⁵² Because they regard varicose veins associated with deep venous obstruction as compensatory, they believe that clinical tests should be supplemented by venography in case the state of the deep circulation is uncertain Should the deep veins be found obstructed, recurrence after operation for varicose vein must, they say, be expected Thus, a knowledge of the state of the deep circulation may warn against operation My comment is that varicose veins do not forward venous blood against gravity Therefore, a collateral circulation by nonvaricose veins must have been established after a deep thrombophlebitis, if the lower leg is not observed to be grossly congested and cyanotic If this is true, — and it seems unassailable to me, — obliteration of varicose veins must always be of benefit, regardless of the state of the deep circulation, and need not result in recurrence Phlebography, however, should give a more complete picture of varicosity in complicated cases than routine tests and should permit a more accurate operation

Arterial spasm, secondary to ligation and retrograde injection of varicose veins is discussed by Tunick, Nach and Weinkle⁵³ These writers studied the resulting arterial constrictions by oscillometry in 50 cases of saphenous varicosity so treated They agree with DeBailey, Burch and Ochsner's⁵⁴ earlier observation that irritation of a venous segment causes reflex arterial spasm This spasm corresponds in degree to the violence of the local reaction Clearly it may be very dangerous, in the presence of states of arterial deficiency, and it perhaps accounts for some of the cases of gangrene of a leg that rarely result from varicose-vein operations

As a final word on the thromboembolic problem, I quote parts of two recent editorials, which should of course be read in toto Allen³⁹ writes

Due to the immensity of the problem in the Massachusetts General Hospital, there has come about a gradual but steady trend toward femoral-vein interruption as an answer to this question. To August 1, 1945, 861 patients in this institution have been subjected to femoral-vein interruption. At first, attempts were made to determine whether or not a thrombus existed, by phlebography — now this method has been abandoned. Early, we learned that the apparent sick leg might be misleading and that often the most dangerous thrombosis was lying dormant in the opposite, apparently normal, side. Therefore, we have gradually become convinced that bilateral interruption should be done.

In this series, there has been no fatality as a result of the procedure. There have been surprisingly few instances of infection or lymphorrhea. Only one of the patients has developed a postphlebotic ulcer. The average hospital stay after femoral-vein interruption has been about six days. Patients operated upon before leg swelling develops have no postoperative edema worthy of note. If the operation is undertaken after bland thrombosis has become inflammatory with pain and swelling, then a period of postoperative edema occurs.

This operation is so safe and so simple and if done on the normal vein produces so little swelling of the extremity, that prophylactic vein interruptions are being done with greater frequency. Up to the date of this writing, this procedure has been carried out in approximately 100 patients in our clinic. All of this group have been elderly patients, who, for reason of their acute disorders, would need a prolonged period of bed rest. Typical of these are the aged with fractures of the hip region.

Allen goes on to allude to the tentative use of dicumarol in his clinic by which fewer operative interruptions may be needed. Collier⁴⁰ writes

The formation and propagation of thrombi in the vascular tree must be prevented by promoting normal physiologic processes, if the process is initiated it must be stopped. The measures used by the surgeon must be simple, readily available and effective. The treatment of thromboembolism as a complication must neither affect adversely the primary disease nor interfere nor complicate the treatment which is essential to this disease. The morbidity and mortality associated with the accepted therapy must be minimal. When these criteria are fulfilled, the problem of thromboembolism will no longer be a problem.

OBSTRUCTION AND THROMBOSIS IN VARIOUS VEINS OF THE BODY

Primary thrombosis of the axillary vein is discussed by Roelsen,⁴¹ who has observed 7 verified cases. He describes the usual swelling, heaviness and congestion of the arm, associated with dilated veins about the shoulder. Apparently these same signs may develop in the absence of actual thrombosis, for obscure reasons. Roelsen finds heparin useful in the acute stages of axillary thrombosis, is opposed to operative interference (resection) except in chronic or recurring disease and advises against immobilization of the arm.

The superior vena caval syndrome is exhaustively described by Hussey, Katz and Yater.⁴² Obstruction of the superior vena cava has received renewed attention since phlebography and measurements of venous pressure have become available. The disorder is usually secondary to thoracic tumors and to aortic

aneurysm, but may also result from the establishment of a fistula between an aneurysm and the great vein. The symptomatology, according to these authors, is related not only to the caval obstruction itself but to the underlying disease as well. Thus, dilated veins on the neck, chest and arms are frequent, and edema is often present in this same field. Dyspnea and cyanosis could equally well be related to the venous obstruction and to the intrathoracic growth or aneurysm. The authors describe methods of measuring venous pressure and present many striking phlebograms. They call attention to improvement that may result from the irradiation of radiosensitive growths and to the occasional value of surgical exploration.

Elective occlusion and excision of the portal vein is discussed by Brunschwig, Bigelow and Nichols.⁴³ The matter came up, in their experience, because of injury to the portal vein in the resection of a malignant pancreatic tumor. Finding, in an autopsy on their patient, that gradual occlusion of the mesenteric veins had resulted in many anastomoses with the vena cava, they undertook experimental occlusion of the portal vein in laboratory animals. Omentopexy was found to be useless, but if the portal vein was gradually severed by a loop of linen thread, subsequent resection of the vein was compatible with normal life in 2 of their 4 animals.

VARICOSE VEINS

In my last review, I¹ called attention to publications recognizing the significance of anatomic relations and venous pressures in the etiology and treatment of varicose veins. Possible dangers in the retrograde injection of sclerosing solutions were also considered. Since then, a swing toward increasingly radical operations has become plainly evident, and local anatomic variations in the groin and thigh have again been emphasized.

A thorough study of the saphenous vein and its tributaries near its entrance into the common femoral vein, based on anatomical dissections in 550 cases, is offered by Daseler, Anson, Reimann and Beaton.⁴⁴ A great variety of patterns are pictured. With such information in mind, a surgeon can have no excuse for not thoroughly eradicating all connections between the varicose saphenous system and the valveless deep veins in the region of the inguinal ligament and above. I am never tired of pointing out that this, of course, is the chief consideration in the successful treatment of varicose veins.

Sherman's⁴⁵ anatomical studies of the connections of the superficial with the deep veins of the thigh have led him to perform a stripping operation, under a general anesthetic, combining this with retrograde injection of a sclerosing solution into the lower saphenous stump, to control the bleeding that might otherwise result from the rather rough eradication of so many saphenous branches. Employing early ambulation, in a considerable series

CASE 32321

PRESENTATION OF CASE

A twenty-eight-year-old bipara entered the hospital complaining of pain in the lower abdomen.

About two years before admission attacks of moderately severe, steady, aching, nonradiating, bilateral, lower abdominal pain began, occurring two or three days before each menstrual period and lasting until the end of the flow. Occasional sharp stabbing pains were also noted. Similar episodes of dull aching and sharp twinges in both lower quadrants, varying greatly in intensity and duration, were present intermittently throughout the month. Concomitantly the periods, which had previously occurred regularly every twenty-eight days, became irregular, and the flow became variable, lasting three to seven days. The patient passed many clots and sometimes had cramps at the time of passage. Her condition gradually increased in severity, and during the few months before admission she had lost 18 pounds. Her last menstrual period occurred seven days before admission.

The patient had been healthy except for two attacks of pneumonia in childhood. Catamenia had begun at the age of thirteen years and had always been regular until the present illness, although she had had cramps during the first day or two of the period, until the birth of her first child six years before admission. After her second pregnancy, three years later, she had been told that there was a cyst in the right ovary. Both babies had been delivered at full term by forceps, the second being a breech delivery. The breasts had become slightly tender before each period.

Physical examination showed a young woman who appeared entirely normal except for an irregular pelvic mass in the lower right vault, with a ridge extending across the posterior cul-de-sac behind the upper cervix.

The temperature, pulse and respirations were normal. The blood pressure was 110 systolic, 80 diastolic.

The urine, blood and hemoglobin were normal, and the blood Hinton reaction and a chest x-ray film were negative.

Because of a mild upper respiratory infection, with moderate nasal discharge and a reddened throat, operation was delayed until the seventh hospital day.

DIFFERENTIAL DIAGNOSIS

DR. HOWARD ULFELDER: This patient was a young mother with symptoms referable to a pelvic mass of several years' duration. Although the history and the physical findings increase the likelihood of one diagnosis over others, the results of the studies are not conclusive and merely suggest strong possibilities.

Several points in the history seem to bear on the problem. The patient had been in fairly good health and had had two children, three and six years old. The marital history had been uneventful until the time of the present illness, when both the duration and the interval of the periods became irregular. The history suggests that true menstrual cramps had not been noted until the onset of the present illness, when she noticed bilateral lower abdominal pain that seemed to be worse at the time of the periods. Apparently the symptoms had gradually grown severer, without any abrupt change. The loss of 18 pounds during a few months is noteworthy, but I should like to know more about the appetite and food habits before attempting to evaluate the significance of the weight loss.

Physical examination revealed an irregular mass in the right vault and posterior cul-de-sac. One would like to know whether the physical examination showed evidence of weight loss. One would also like to know the size of the mass and whether it was tender or movable, and whether the uterine fundus and cervix appeared abnormal in any way.

DR. OLIVER COPE: So far as weight loss is concerned, the patient was not conscious of any change in her food habits but realized that her appetite was impaired. She felt generally less well. The physical examination was entirely negative except for the mass in the pelvis, which could be felt behind the cervix, better by rectum than by vagina. The prominent part was more to the right side than to the left. The mass was small, plum-sized, quite hard and, apparently, adherent to the upper part of the cervix or to the lower part of the uterus. The fundus of the uterus was normal in size, was freely movable, and could be distinctly felt, because the patient was quite thin. The mass, which was principally on the right, extended over to the left with a suggestion of irregularity and of diminishing size, disappearing into the left vault. Neither ovary was identifiable, but there was apparently nothing higher up in the vault. The cervix showed minor erosions compatible with two pregnancies.

surgical castration and closure of the incision, with subsequent castration by x-ray

DR. ULFELDER My decision in this case would have depended on my evaluation of the patient — whether she wanted more children, and how she would react to the idea of surgical castration. It would make a difference whether the possibility of castration had been discussed before operation.

DR. FRANCIS INGERSOLL I do not believe that I should have castrated the patient at the time, not knowing the entire story, because endometriosis is known to be slow in development. Many patients whose entire ovarian tissue appears destroyed by endometriosis of both ovaries have later had children with apparent ease. I remember one such patient who has had three children and is again pregnant. The lesion is not malignant and can be checked at any time with x-ray treatment. It therefore seems wise to me to leave the ovaries and see what happens in the future, the status of the disease may not change for years.

DR. BENJAMIN CASTLEMAN Did this patient show signs of obstruction of the colon?

DR. COPE No. About one third of the circumference of the sigmoid was involved. That fact entered very decidedly into the decisions in handling the case, because I believed that any extension of the disease would have caused intestinal obstruction. We had made a tentative diagnosis of endometriosis preoperatively and had discussed the possible implications with both the patient and her husband. I was also influenced by the facts that the patient had been examined by competent hands and that the disease had appeared in six months and was considered to be growing rapidly, and I believed that intestinal involvement had something to do with the weight loss. In other words, we were dealing with a rapidly progressing lesion whose major involvement was in the gastrointestinal tract. The patient had two children and desired no others. Both husband and wife were reconciled to the idea of castration if that proved necessary. We therefore decided on castration, and we resected the ovaries rather than waiting for additional information. In fact, we thought that the disease had progressed to the point of requiring castration by one method or another.

Dr. Ingersoll's point is well taken, but I was not sure that another pregnancy would occur. The patient faced a very disagreeable time whichever decision we made. I hate to castrate anybody, particularly a woman of her age. But it seemed worse to allow her to face a permanent colostomy. How soon can the patient be safely relieved of the disagreeable symptoms of the menopause by partial replacement therapy? It seems obvious that adequate replacement therapy is contraindicated because the endometriosis would be stimulated to a tumorous growth. Can enough replacement therapy

be given to help the patient through the uncomfortable period after acute menopause?

DR. ULFELDER I believe that symptoms would flare up again regardless of what was done.

DR. INGERSOLL Theoretically, the symptoms could be exacerbated by estrin, which could, however, be used for temporary improvement and control of the hot flashes.

CLINICAL DIAGNOSIS

Endometriosis

DR. ULFELDER'S DIAGNOSIS

Endometriosis

ANATOMICAL DIAGNOSIS

Endometriosis of sigmoid, rectum, bladder and left ovary

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN The material we received showed a tiny area of endometriosis on the back of the left ovary, and none on the right. The biopsy specimen that Dr. Cope took from the dome of the bladder and sigmoid also showed endometriosis. Dr. Cope's point about involvement of the sigmoid is important because resection of the sigmoid has been necessary in almost all the cases with involvement of the sigmoid that have been seen in this hospital. I do not believe that x-ray treatment would have relieved the obstruction, once the scarring had gone so far as to produce obstruction of the sigmoid. Resection of the sigmoid would have been necessary.

DR. COPE That point is worth emphasizing. We thought that the intestinal lesion was potentially malignant and that extreme measures were required from an endocrinologic point of view. The disease, of course, was not malignant, but its distribution was

CASE 32322

PRESENTATION OF CASE

A forty-five-year-old housewife entered the hospital because of postprandial pain.

About two years before admission the patient first noticed attacks of stomach pain that occurred one or two hours after eating. The pains became progressively worse, and nausea and vomiting developed. Prescribed medication and diets gave no relief. X-ray studies seven months before admission were said to have shown an ulcer. During the illness the patient had lost 45 pounds, but she had regained some weight in the last few months, apparently as the result of marked symptomatic relief obtained from a new regime of diet and medication.

Four years before admission a hysterectomy had been performed for fibroids.

DR ULFELDER Was the mass movable and nontender?

DR COPE No, it was fixed and slightly tender

DR ULFELDER Abdominal and chest films, a barium enema, an Aschheim-Zondek test and anything that might give some clue regarding the nature of the palpable mass would be helpful I believe that only a plain abdominal film and a chest film were really indicated, since surgery was imperative and the risk of operation minimal Was an abdominal film taken?

DR COPE No, it was not And a barium enema was not given because the mass seemed clearly to be in the posterior cul-de-sac We doubted whether a barium enema would show anything

DR ULFELDER That was my opinion from the history

DR COPE I also doubt whether a plain abdominal film would have shown anything An x-ray film of the chest was taken in spite of the negative physical examination, on the principle that in a patient who had lost so much weight tuberculosis should be excluded

DR ULFELDER This lesion must have been of several years' duration The change in menstrual habit strongly suggests sufficient involvement of both ovaries to interfere with normal ovulatory rhythm Three diagnoses appear possible in this case involvement of both ovaries in an ovarian tumor, endometriosis and chronic pelvic inflammatory disease Nothing in the history supports the last diagnosis The pregnancies three and six years before admission militate against, although they do not actually exclude, endometriosis The pain with the periods and the description of the mass, especially in the cul-de-sac, are points in favor of endometriosis The most probable ovarian tumor in this patient is dermoid, and dermoid is bilateral in about 20 per cent of cases Mention should also be made of unilateral ovarian tumor, with endocrinologic activity with the production of estrin Granulosa-cell tumor is the most frequent of such lesions Tuberculosis must also be excluded

My diagnosis is endometriosis, in spite of the fact that the patient had recently had children The likeliest type is endometriosis involving both ovaries and the adnexa in the usual fashion, and I base this diagnosis on the history of pain with the periods and the finding of a fixed mass in the vault extending down into the cul-de-sac

DR COPE Examination under ether revealed nothing beyond what had been observed without anesthesia We did not definitely identify the ovaries apart from the mass (I hope Dr Ulfelder will comment on these findings later) When we dilated the cervix to see what the endometrium looked like, we could easily look up into the cervix, where there were small, 2-mm long, firm, polypoid irregularities, which did not bleed easily but were a matter of concern in judgment of what was sub-

sequently done This was not the usual fleshy type of polypoid mass that eventually extrudes from the cervical canal The endometrial tissue was whitish, consistent with a postovulatory phase, and was grossly somewhat firm, as if slightly fibrosed, but was considered normal The uterine cavity was obviously normal, except for the mass that was adherent behind to the upper cervical segment The lower part of the uterus was lobulated and larger on the right, so that the mass might have been taken for a cervical fibroid, but I did not believe so On opening the abdominal cavity exploration was negative, except that the tip of the appendix was definitely bulbous, as in a carcinoid appendix—the patient had had no recent attack suggesting a subsiding inflammation The uterus was normal Both ovaries and tubes were grossly normal, except for one small area behind the left ovary, which contained a small punctate bluish cyst On the dome of the bladder on the left side was a puckered area of fibrous scarring, with retraction not more than 1 cm in diameter containing a half dozen small blue cysts This area was later excised and given to Dr Castleman That was all the disease, except for the mass in the pelvis, which proved to be the rectum and sigmoid involved in three areas of endometriosis, the upper rectum and sigmoid were puckered and attached firmly to the back of the upper part of the cervix and the lower part of the uterus From this description it can be seen that we agreed with Dr Ulfelder's diagnosis

At first excision of the three areas of endometriosis appeared possible We divided the peritoneum 0.5 cm away from the areas of gross endometriosis and began to dissect down the sigmoid in the muscular layer The first area of endometriosis on the sigmoid was resected easily enough, the second with slightly more difficulty When the rectum was reached it was clear that the third area could not be resected the disease had infiltrated so deeply into the muscular wall that it would have been necessary to resect the rectum More careful inspection of the areas of the sigmoid that had been freed showed that the disease had penetrated into the muscularis When the muscular layer of the sigmoid was opened two cysts popped out, and deep invasion was unmistakably present We did not know whether the disease extended to the mucosa itself, but it clearly went deeply into the mucosal layer, and to resect the tissue, a combined resection of the sigmoid and rectum, with a permanent colostomy, would have been necessary I should like Dr Ulfelder and others to comment on what they would have done at this stage

DR ULFELDER Such a decision is extremely difficult in a patient under thirty years of age

DR COPE The endometriosis was limited to one area on the left ovary and to one on the bladder that was resectable and localized to the rectum, sigmoid and back of the uterus The two alternatives were

Medicine*, 8 Fenway, Boston 15, Massachusetts

To date, the progress of the Study has been most encouraging. Throughout the country most of the state programs are being promulgated by experienced physicians who have returned from the war realizing that a new order is in the offing. Before resuming their former activities, they have been challenged by this opportunity to take inventory of one part of medical practice.

The Study may now be said to have been completely organized. Programs are under way in all the states, and regional conferences have been planned for the early fall to consider the form that national and state reports should take. Substantial funds, largely from voluntary sources, have permitted the work to be carried on with the proper perspective for a work of national proportions. In New England, substantial contributions have been made by the National Foundation for Infantile Paralysis, and in Massachusetts, by the newly formed Bay State Society for the Crippled and Handicapped. In all the New England states, the project is not only launched but well afloat. Rhode Island has practically completed its part in the survey. A pilot study, already finished in North Carolina, has clearly shown that physicians busy in practice regard this as something more than just another survey and that pediatricians consider it a serious responsibility.

The national committee is now considering how to make the best use of material from the questionnaires. In the near future, it will be possible to announce the statistical methods that will be adopted. Although it is clear that many already know deficiencies in medical care will be re-emphasized, it is expected that new light will be shed on the amount of service contributed by practitioners of medicine and dentistry, on the quality of service available in clinics and institutions and on the actual scope of present pediatric practice. All these data should form a basis for future concerted action on the part of pediatricians to improve and extend present health services to children.

Already important side lights of the Study have been observed. It is making legislators reluctant to advance new panaceas for the improvement of medical care until the questionnaires are processed. Furthermore, a great awareness of the importance

STUDY OF CHILD HEALTH SERVICES

THE medical profession has been well informed through editorials in the *Journal* and the *Journal of the American Medical Association* and through the public press of the Study of Child Health Services. It warrants reiterating that the study is being conducted not only by the members of the American Academy of Pediatrics but by all pediatricians, who, in co-operation with physicians and dentists, are applying a technique to evaluate medical service in one large segment of the profession. It is hoped that this and the recent study of the Commission on Hospital Care will be supplemented by other similar investigations in order that all facts on which physicians can intelligently plan a better and more equitably distributed form of medical care will be available.

Physical examination revealed little except tenderness in the epigastrium, without spasm or a mass. The tongue was heavily fissured, with smooth red edges.

The temperature was 98.6°F, the pulse 100, and the respirations 24. The blood pressure was 130 systolic, 80 diastolic.

The hemoglobin was 12.5 gm per 100 cc. The urine had a specific gravity of 1.018 and gave a + test for albumin. The serum protein was 5.9 gm per 100 cc. A gastrointestinal series revealed a large ulcer crater on the lesser curvature of the stomach midway between the cardia and angulus, which measured 3.5 cm at the base and was surrounded by a wide collar of edema. The remaining portion of the stomach and the intestines were normal. Gastric analysis yielded 120 cc of fluid with 7 units of free hydrochloride after fasting, 48 cc with 23 units after alcohol and 130 cc with 57 units after histamine.

The patient was maintained on a medical regime for a month, during which she gained weight and was subjectively improved. Re-examination of the stomach by x-ray showed the lesion to be unchanged.

An operation was performed on the forty-third hospital day.

DIFFERENTIAL DIAGNOSIS

DR. WADE VOLWILER: Two years' duration of ulcer symptoms in no way rules out the presence of a slowly growing neoplasm, for in many authenticated cases the patients have had symptoms for several years. The initial regime of diet and medication in the case under discussion gave imperfect relief of ulcer pain, and nausea with vomiting was a prominent feature. These symptoms are somewhat suggestive of gastric cancer. It is probable that the weight loss was due to simple starvation from anorexia and vomiting, rather than to the presence of widespread neoplasm. The tongue abnormalities suggest a prolonged inadequate diet.

The large size of the ulcer crater is statistically somewhat in favor of cancer, but statistics are not of great aid in single cases. I am not furnished with the necessary information relative to the peristaltic activity in the ulcer area, and to the presence or absence of rigidity of the gastric wall. I should like to know if the contour of the ulcer crater was perfectly smooth. The presence of free hydrochloric acid does not rule out cancer. Although the patient gained weight and had less discomfort, the ulcer crater did not change in size during a full month's careful observation under hospital conditions. Even

very large benign ulcers should show some diminution in size during this interval on a proper therapeutic program. It is possible that expert gastroscopy early in the hospital stay would have prevented a month's operative delay if neoplasm were actually present.

The choice of an exact diagnosis in this case is not possible. The important fact is that the ulcer did not change during a month's ideal regime, and therefore surgical extirpation was properly decided on and accomplished. The information is about equally divided in favor of a malignant and a benign lesion. If malignant, this was probably a slowly growing carcinoma, similar ulceration in a lymphoma occurs in this area, but is infrequent. Since I must make a choice, I shall cast my vote in favor of a gastric carcinoma.

CLINICAL DIAGNOSIS

Carcinoma of stomach?

Gastric ulcer?

DR. VOLWILER'S DIAGNOSIS

Carcinoma of stomach

ANATOMICAL DIAGNOSIS

Benign gastric ulcer, with penetration into pancreas

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: The first impression of the roentgenologist who examined this patient and also of the clinician on the ward was that they were dealing with a benign ulcer. It was decided to give the patient a therapeutic test of three weeks of adequate medical and dietary treatment. When this failed to produce any sign of improvement in the lesion, their confidence was shaken and they began to fear that it must be carcinoma. For this reason operation was undertaken.

On exploration a large ulcer was found on the lesser curvature, which was densely adherent to the pancreas. It proved impossible to separate the stomach from the pancreas, and a portion of the pancreas was therefore resected along with about two thirds of the stomach. It was fortunately possible to do this without interfering with the splenic vessels. The resected specimen showed a sharply punched-out ulcer crater measuring 3 cm in diameter. The base of the ulcer was formed by pancreatic tissue. Numerous sections from the walls of the ulcer showed no evidence of cancer.

ient of his affliction The danger arising out of de Kruif's article is best brought out by Commissioner Anslinger's own words

I fear a wave of Demerol addiction if physicians who read this article believe what I consider the reckless and dangerous statements made by de Kruif that the drug is free from addiction properties This is information somewhat similar to that which appears in the circular distributed by the manufacturer of Demerol to push sales Had this article been prepared on a strictly scientific basis, it would have sounded a strong warning about the danger of addiction Our files contain numerous cases of addiction involving the use of Demerol I cannot too strongly warn the members of your association about the danger of addiction to Demerol

The *Reader's Digest* is not noted for retracting erroneous statements that appear in its articles It might do well to start now by publishing Mr Anslinger's letter prominently in a subsequent issue

COMMENT

Diseases reported at an incidence above the seven-year median included chicken pox, diphtheria, German measles and measles

Measles was reported at a record high for the month of June but had decreased from the peak of 11,501 cases reported in May

Diseases reported below the median included poliomyelitis, meningococcal meningitis, mumps, lobar pneumonia, scarlet fever and whooping cough

Lobar pneumonia was again at a record low for the fifth successive month

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Diphtheria was reported from Boston, 6, Brookline, 2, Chelsea, 2, Gloucester, 2, Lancaster, 1, Lowell, 2, Somerville, 1, Taunton, 4, Worcester, 1, total, 21

Dysentery, bacillary, was reported from Lexington, 2, total, 2

Encephalitis, infectious, was reported from Worcester, 1, total, 1

Hookworm was reported from Wellesley, 1, total, 1

Malaria was reported from Belmont, 1, Boston, 15, Brockton, 1, Chicopee, 1, Clinton, 1, Dedham, 2, Douglas, 1, Easthampton, 1, Everett, 1, Fitchburg, 2, Foxboro, 1, Greenfield, 1, Haverhill, 1, Hingham, 1, Lawrence, 2, Lunenburg, 1, Lynn, 2, Malden, 1, Marlboro, 1, Medford, 2, Merrimac, 1, Montague, 1, New Bedford, 1, Newton, 1, Oxford, 1, Salem, 1, Saugus, 1, Salisbury, 1, Springfield, 3, Stoneham, 1, Taunton, 1, Warren, 1, Watertown, 1, Worcester, 2, total 56

Meningitis, meningococcal, was reported from Bröckton, 1, Malden, 1, Newton, 1, Watertown, 1, total, 4

Meningitis, Pfeiffer-bacillus, was reported from Springfield, 1, total, 1

Meningitis, pneumococcal, was reported from Fall River, 1, Mattapoisett, 1, total, 2

Meningitis, streptococcal was reported from Springfield, 1, total, 1

Meningitis, undetermined, was reported from Belmont, 1, Haverhill, 1, Marblehead, 1, Millbury, 1, Saugus, 1, Weymouth, 1, Worcester, 1, total, 7

Psittacosis was reported from Cambridge, 1, total, 1

Salmonella infections were reported from Boston, 1, Cambridge, 4, Chelsea, 3, Lexington, 1, Lynn, 5, Malden, 4, Newton, 3, South Hadley, 1, Springfield, 1, Swampscott, 2, Winthrop, 9, Worcester, 3, total, 37

Septic sore throat was reported from Amesbury, 1, Boston, 3, Mansfield, 1, total, 5

Tetanus was reported from Methuen, 1, Pittsfield, 1, Quincy, 1, total, 3

Trichinosis was reported from Boston, 2, total, 2

Typhoid fever was reported from Lowell, 1, Somerville, 1, Worcester, 1, total, 3

Undulant fever was reported from Boston, 1, Hanson, 1, Haverhill, 1, total, 3

CORRESPONDENCE

BOOKS FOR DEVASTATED LIBRARIES

To the Editor During the war, the libraries of half the world were destroyed by the impact of battle and in the fires of hate and fanaticism Where they were spared physical damage, they were impoverished by isolation There is an urgent need — now — for the printed materials which are basic to the reconstruction of devastated areas and which can help to remove the intellectual blackout of Europe and the Orient

The need is so urgent, scientists working in Europe are so handicapped, that surely those of us working near well equipped libraries will be willing to sacrifice the convenience of an "office copy" in order to provide library facilities for less fortunate colleagues

There is need for a pooling of resources, for co-ordinated action so that the devastated libraries of the world may be restocked so far as possible The American Book Center for War Devastated Libraries Incorporated, has come into being to meet this need It is a program that is born of the

of child care is being created throughout the United States. Finally, it has shown that the only way for federal agencies to understand the problems of medical practice is to work with physicians.

DEMEROL IS HABIT FORMING

IN A letter to the editor of the *Journal of the American Medical Association*,* H. J. Anslinger, Federal Commissioner of Narcotics, calls attention to the work of experts of the United States Public Health Service and others who brought forth convincing evidence of the habit-forming properties of Demerol. He also refers to the article by Paul de Kruijff in the June issue of the *Reader's Digest* entitled "God's Own Medicine — 1946," which appeared under the headline "The pain-fighting power of demerol is as miraculous as that of morphine — without the opiates' danger of addiction."

"This article," Mr. Anslinger points out, "adroitly makes no reference to the work of Dr. C. K. Himmelsbach of the United States Public Health Service and Drs. Hans H. Hecht, Paul H. Noth and F. F. Yonkman of Detroit, all of whom warned of the danger of addiction." "Demerol," he continues, "was placed under federal narcotic control by the Congress because of evidence given before that body of its dangerous properties. Some of the persons referred to in de Kruijff's articles could have attended the hearings before the Ways and Means Committee and have testified as to what they thought about the drug, but they elected to remain silent."

Time and again, the general public has been treated to great "scoops" in newspaper and magazine articles by enthusiastic writers of popular science and medicine. Most successful among such writers have been those who dramatize the great advances in medicine, and their writings have proved extremely remunerative. It seems likely that they are often encouraged by the sales-promotion divisions of manufacturers, particularly those of companies that hold patent rights to the remedies in question.

Usually such articles, when properly written and carefully edited, serve the useful purpose of educating the public concerning what they may expect

from the medical profession. At times they also serve to stimulate the laggard physician to keep up with medical progress. Careful editing by scrupulous, well informed and critical medical authorities is, however, quite essential to assure that the public learns only established facts and is not treated to half-truths or to unwarranted or premature deductions based on enthusiastic interpretations of preliminary observations or of limited and uncontrolled studies.

Unfortunately the urge to scoop or to be sensational has often resulted in the substitution of drama for truth, and popular appeal has often been placed ahead of the public good. Readers are presented with half-truths or with what they want to hear rather than with the unadulterated facts concerning what has actually become available. The favorable aspects of discoveries are emphasized, whereas their limitations and their possibilities for harm are all too frequently ignored or minimized.

When a new discovery in medicine concerns an item of vanity, such as a cure for baldness or for gray hair, the medical profession should be interested chiefly in ascertaining that the possibilities for harm have not been overlooked. That is particularly true, for example, of the many remedies for obesity and the so-called "rejuvenators," which have been heralded with enthusiasm by popular writers.

Great harm may also be done by giving false hopes to the poor sufferers of incurable disease or by encouraging those who require prolonged observation and care with hopes for a rapid cure when such is not actually the case. These misconceptions on the part of patients often serve to break their morale and also to destroy confidence in their physicians, which often plays such an important role in their general welfare.

In the case of Demerol, the danger is quite clearly brought out by Mr. Anslinger. Patients having pain will insist on relief by "God's own medicine," with the *Reader's Digest's* assurance that it is without danger of addiction. Those already addicted to narcotics are also in great danger of substituting one addiction for another. This may prove quite profitable to those who control the German patents on Demerol, but it may turn out to be quite disappointing to the honest physician who is trying to help rid his pa-

SCLEREDEMA: A SYSTEMIC DISEASE*

BERT L. VALLEE, M.D.†

BOSTON

IN 1900, Buschke¹ described the case of a forty-six-year-old carriage painter who suffered from persistent brawny induration of the skin of the face, chest and upper extremities. Following influenza, firm, nonpitting edema started in the neck and spread centrifugally. There was marked chemosis. The patient did not appear ill, had lost no weight, had no fever and had no complaints other than immobility of the skin. Buschke thought this picture to be distinct from those of previously reported syndromes and called the disease "scleredema adultorum."

Many papers have since appeared in Germany delineating and expanding the original concepts,²⁻²⁹ and a few reports were published in other European countries in the following thirty years,³⁰⁻³⁵ but it was not until 1932 that the first note appeared in this country, when Epstein³⁶ reported 2 cases and reviewed the 41 cases previously described. Since then many publications have appeared,³⁷⁻⁷⁵ and the disease is readily recognized. The 4 patients to be described herein were all observed at Mount Sinai Hospital within the last six years.

CASE REPORTS

CASE 1 (M S H 454642 and 472542). A 35-year-old German was admitted on April 3, 1940, 11 weeks following a sore throat and tonsillitis with elevation of temperature that lasted a few days. Four weeks after the onset of sore throat, the patient noted thickening and tightening of the skin of the back of the neck, which gradually spread to involve the trunk, arms and upper abdomen. Intravenous typhoid vaccine and short-wave and calcium therapy were without benefit.

Physical examination revealed a well-developed man with masklike, oily facies. Both eyelids were puffy. There was slight restriction in opening of the jaws and protrusion of the tongue. The blood pressure was 120/80. The skin felt strikingly inelastic, thick, indurated and bound down to the underlying tissue over the face, chest, neck, back, abdomen and upper extremities. The hands were minimally involved, and the lower extremities were normal.

The urine was normal and had a specific gravity of 1.031. A blood Wassermann test was negative. The blood urea nitrogen was 10 mg per 100 cc, the sugar 80 mg, the cholesterol 280 mg, the cholesterol esters 165 mg, the phosphorus 3.8 mg, the calcium 11.2 mg, the total protein

6.5 per cent, and the creatinin 2.8 mg. A creatinin tolerance test showed no significant change. The basal metabolic rate ranged from -11 to -39 per cent. X-ray examinations of the chest, neck and skull were negative. Electrocardiographic tracings showed low voltage and an inverted T₄. Biopsy of the skin over the deltoid region revealed no abnormality. The sugar-tolerance curves ranged from 75 to 95 mg per 100 cc.

Desiccated thyroid was given in doses up to 0.7 gm daily, but without benefit. Hyperthermia was tried, and the patient experienced loosening of the skin following each treatment for several hours, but there was no lasting relief.

The patient was discharged after 3 weeks and was observed in the Out Patient Department for 1 year. On April 29, 1941, he was readmitted to the hospital for further study. During this interval there were only minor fluctuations in the stiffness and induration of the skin.

The findings on readmission were essentially those of the first admission. The hemoglobin was 88 per cent (Sahli) and the white-cell count 9950, with a normal differential count. The basal metabolic rate on two occasions was -4 and -10 per cent. A test showed sweating to be markedly reduced over the entire body. The sugar-tolerance curve was normal. The chloride was 595 mg per 100 cc, the alkaline phosphatase 10 K-A units, the albumin 5.1 gm, the globulin 1.6 gm, and the icteric index 6. The other blood chemical findings were essentially those during the first admission. Throat cultures revealed beta-hemolytic and alpha-hemolytic streptococci. The urine was negative, as were electrocardiographic tracings. A biopsy of the left deltoid region showed swelling of the collagen bundles of the corium and subcutaneous tissue. With *Kresleychiviolet* a faint pink-staining intercollagenous substance, such as that described by Freund³² was demonstrated. The histologic findings were interpreted as consistent with scleredema adultorum.

On the 13th hospital day, treatment with 3 cc of dihydro-tachysterol daily was begun, and after 2 days this dosage was increased to 5 cc. After 12 days of this therapy, the patient manifested severe toxic symptoms characterized by malaise and vomiting. The calcium blood level was 14.5 mg per 100 cc. The skin seemed to have softened, although there had been no dramatic improvement. The patient was discharged at his own request after 2 months of hospitalization.

Follow-up examination in December, 1944, showed the skin of the upper extremities to be hard and inelastic. The masklike facial expression was still present, although the cutaneous changes of the thorax, abdomen and neck had disappeared.

CASE 2 (M S H, O.P.D. 40-4027). The patient, a 16-year-old Puerto Rican girl, had been in good health until April, 1940, when she developed pneumonia with subsequent empyema necessitating surgical drainage. One month after recovery she developed sudden swelling of the back of the neck, face and scalp, with difficulty in moving the head from side to side. In a few days the swelling spread to involve the shoulders and upper arms.

Physical examination revealed a young girl with a hard edema in the areas previously described. The skin was taut, had a rubbery consistence and did not pit on pressure. There was no affection of the underlying muscles. The blood pres-

combined interests of library and educational organizations, of government agencies and of many other official and non-official bodies in the United States.

The American Book Center is collecting and is shipping abroad scholarly books and periodicals which will be useful in research and necessary in the physical, economic, social and industrial rehabilitation and reconstruction of Europe and the Far East. The Center cannot purchase books and periodicals, it must depend on gifts from individuals, institutions and organizations.

Medical and scientific books and periodicals constitute the most important type of material needed and it is needed now. We feel sure that members of the Massachusetts Medical Society and other readers of the *Journal* will want to help their suffering colleagues in war-torn Europe and Asia.

WHAT IS NEEDED Scholarly books published in the last decade in general science and technology, medicine and the allied sciences, dentistry, chemistry, physics, biography, the social sciences, the fine arts and fiction of distinction. Scholarly scientific books will be especially welcome even if not the last edition of a standard work so long as the book has been published in the last decade. Periodicals in any of the above subjects, including runs of volumes, single volumes and even single issues. Large quantities of the more usual journals are needed, such as *Science*, *Proceedings of the Society of Experimental Biology and Medicine*, *Journal of the American Medical Association*, *Surgery, Gynecology and Obstetrics*, *American Journal of Surgery*, *New England Journal of Medicine*, *New York State Medical Journal*, *Southern Medical Journal*, *Journal of the Association of American Medical Colleges*, *American Journal of Public Health*, *U S Public Health Reports Weekly* and journals in the special sciences and clinical specialties. If in doubt, a list of titles available should be sent direct to headquarters before shipping, giving a rough idea of dates and volumes, the inquirer will be informed whether the material offered meets requirements.

WHAT NOT TO SEND State journals or journals of purely local interest other than those listed above, old transactions of medical societies, material of ephemeral interest, outdated textbooks and monographs, students' compends, annual reports or local state documents, material of doubtful importance published by commercial firms, schoolbooks, books for children or young people, light fiction, material of local interest and popular magazines.

How to SHIP All shipments should be sent *prepaid* via the cheapest means of transportation to the American Book Center, c/o The Library of Congress, Washington 25, D C. Although the Center hopes that donors will assume the costs of transportation of their materials to Washington, when this is not possible reimbursement will be made on notification by card or letter of the amount due. The Center cannot accept material that is sent transportation collect. Reimbursement cannot be made for packing or other charges beyond actual transportation costs. When possible, periodicals should be tied together by volumes. It will be helpful if missing issues are noted on incomplete volumes. It is hoped that many will feel that they can make part of their contribution the payment of transportation of material as far as Washington.

Division of Medical Literature, American Book Center
Joint Committee on Books for Devastated Libraries
Library of Congress
Washington 25, D C

HUNGER EDEMA

To the Editor In the editorial "Avitaminosis and Hypoproteinemia in Starvation" appearing in the July 4 issue of the *Journal*, reference is made to the reports in the literature of the high incidence of so-called "hunger edema."

I was with an evacuation hospital that took over the Mathausen Concentration Camp in Austria shortly after its liberation in May, 1945. Our experience was slightly different from that reported elsewhere. Edema, regardless of a severe state of nutrition, was rare. We gave these persons plasma, whole blood and fluids. Within a few hours or days edema became intense. Many of the patients who had previously been merely a mass of dehydrated skin and bones developed a marked pitting edema extending over the entire

body. Their features were often unrecognizable. Restriction of fluids was necessary to relieve the edema. The blood protein levels before the onset of edema were usually low or normal. Under the Germans, the daily fluid intake had been so restricted that edema formation was impossible. Evidence of gross vitamin deficiency was rare, the only picture resembling that of beriberi.

ROY J. FOXKIN, M.D.

2007 Wilshire Boulevard
Los Angeles, California

NOTICES

ANNOUNCEMENTS

Dr John M. Barry announces that he will resume the practice of medicine in association with Dr. Z. William Colcoa at 215 Bay State Building, Lawrence.

Dr Philip S. Foisie announces the reopening of his office for the practice of surgery at 520 Commonwealth Avenue, Boston.

SEMINAR IN LEGAL MEDICINE

A seminar in legal medicine, sponsored jointly by the Department of Legal Medicine, Harvard Medical School, and the Massachusetts Medico-Legal Society, with the co-operation of the medical schools of Boston University and Tufts College, will be held during the entire week of October 7 to 12. The seminar will cover subjects of particular interest to medical examiners, coroners, pathologists and others interested in medicolegal investigations, and the attendance is limited to twenty. For further information write to Dr. William H. Watters, Harvard Medical School, 25 Shattuck Street, Boston 15.

AMERICAN COLLEGE OF PHYSICIANS

The twenty-eighth annual session of the American College of Physicians will be held from April 28 to May 2, 1947, at Chicago, Illinois. Dr. David P. Barr, of New York City, is president of the College and will be in charge of the program of general sessions and lectures. Dr. LeRoy H. Sloan, of Chicago, has been appointed general chairman and will be in charge of the program of hospital clinics and panels, as well as local arrangements, entertainment and so forth. Mr. Edward R. Loveland, executive secretary of the College, 4200 Pine Street, Philadelphia 4, will have charge of the general management of the session and the technical exhibits.

INDUSTRIAL HEALTH CONGRESS

As previously noted, the Seventh Annual Congress on Industrial Health, sponsored by the Council on Industrial Health of the American Medical Association, will be held in Boston during the week beginning September 30. Headquarters will be at the Copley Plaza Hotel, with some of the meetings scheduled for halls at Harvard University.

Preliminary plans call for meetings of committees and of the Industrial Health Council on September 28 and 29. The first day of the Congress will be given over to a symposium on lead poisoning and to an afternoon surgical conference. A state-society dinner and conference will climax the day. On Tuesday, October 1, there will be a morning symposium on problems in industrial medicine as viewed by labor, management and medicine. Elective conferences are planned for the afternoon, these will cover industrial physiology, administrative methods, aviation medicine and workmen's compensation. A Pan-American dinner and conference will be held in the evening. The third day will highlight medicine and industry in a physicochemical age, and also the place of physical fitness programs in industry, with the Bureau of Health Education of the American Medical Association contributing interesting data. A public dinner for health and welfare leaders, at which a nationally-known industrial leader will be the speaker, will climax the program.

The Congress this year is being co-sponsored by the Council of the New England State Medical Societies.

(Notices continued on page xv)

gs The skin of the feet was spared There was no pigmentation of the skin or scarring anywhere

On physical examination the eyelids were markedly puffed and distorted the face, which was mildly edematous The conjunctivas were swollen and edematous The upper respiratory passages, heart, lungs and abdomen were normal, and neurologic examination was not remarkable There was hard, nonpitting edema of the legs and thighs No pigmentation or scarring was present The feet were spared There was no acral edema The hemoglobin was 70 per cent (Sahl), the red-cell count 3,900,000, and the white-cell count 5000, with a normal differential count The urine was repeatedly negative, as was the blood Wassermann reaction The blood urea nitrogen was 8 mg per 100 cc, the sugar 75 mg, the chloride 595 mg, the cholesterol 292 mg, the cholesterol esters 205 mg, the carbon dioxide combining power 51 vol per cent, the phosphorus 3.4 mg per 100 cc, the calcium 9.5 mg, and the total protein 6.7 gm, with an albumin of 3.8 gm and a globulin of 2.9 gm The hippuric acid excretion was 6 gm, and the galactose excretion 1.5 gm An electrocardiogram revealed no abnormality An electroencephalogram was negative X-ray examination of the skull

disappears and the patient enters an asymptomatic period varying from several days to as long as three months The onset of the edema may be the initial manifestation of scleredema, or there may be a short prodromal period of malaise, myalgia and even low-grade temperature

The appearance of a patient with scleredema is so striking as to suggest the diagnosis immediately The face, neck, thorax, legs and buttocks present an extensive pale swelling The normal mobility of the face is lost The lines are obliterated by a dull, waxy swelling The lack of facial expression suggests the masklike facies of parkinsonism The conjunctivas are thickened and elevated, but the edema ends abruptly at the cornea The eyelids are especially involved (Fig 1), frequently being

FIGURE 1 Case 4

These photographs were taken in June, 1945 Note the marked eyelid changes and chemosis

was negative X-ray examination of the chest revealed no abnormality of the lungs or pleural cavities Fluoroscopy showed the horder of the right heart to be prominent with diminished pulsations, a fact that was confirmed by kymography Intravenous pyelography revealed slight ptosis of the kidneys There was no demonstrable abnormality in the urinary tract The basal metabolic rate was +11 per cent The sedimentation rate of erythrocytes was 29 mm per hour A skin test for trichinosis infection was negative A biopsy specimen taken from the leg showed nothing significant A urine concentration test gave a specific gravity of 1.030, and phenolsulfonphthalein excretion was normal

The patient had been admitted for diagnostic purposes She was afebrile on entry and there was no significant change in her condition during her stay No treatment was administered The disease process was considered to be scleredema adultorum, and the ultimate prognosis was thought to be good She was discharged after 3 weeks of hospitalization

CLINICAL MANIFESTATIONS

In most of these cases of scleredema a febrile illness preceded the onset of the disorder The infections have most frequently been influenza, sore throat, tonsillitis and scarlet fever It is interesting to note that in most cases the initial illness has been streptococcal in origin This acute infection

swollen and red The pallor of the edema is so pronounced that patients are often thought to be anemic, although the dead-white color of scleroderma is lacking The edema is hard and non-pitting On palpation the skin and subcutaneous tissue feel thickened and indurated The affected skin cannot be picked up in folds or creased Occasionally an erythematous or scaly rash affecting the arms and face is transiently present Closer examination of the affected areas reveals that the normal pits and skin markings are well preserved or exaggerated The dermal appendages are not affected

Scleredema most frequently begins in the nape of the neck and spreads to the face, thorax and shoulders Not infrequently the abdomen, lower and upper extremities and buttocks are involved More rarely the tongue and pharyngeal tissues are affected^{29 36 42} The tongue is described as immobile and large, the patient suffering from dysarthria Complaints of dysphagia are referred to scleredema of the pharynx Several observers have noted that

sure was 120/80. The remainder of the physical examination was not remarkable.

The urine was normal. The hemoglobin was 85 per cent (Sahli) and the white-cell count 6300, with a normal differential count. A blood Wassermann test was negative. The blood urea nitrogen was 13 mg per 100 cc, the sugar 75 mg, the calcium 10.6 mg, the phosphorus 4.0 mg, and the alkaline phosphatase 9 K-A units. The sedimentation rate of erythrocytes was not increased. The basal metabolic rate was +8 per cent. An electrocardiogram showed low voltage of the QRS complexes.

The patient was followed for 3 years in the Out Patient Department. She was given numerous hyperthermia treatments and felt considerably improved after each treatment. The swelling gradually receded but was still marked when the patient was last seen 3 years after the onset of the illness.

CASE 3 (M S H 519043 and 525942) A 37-year-old woman was admitted on April 14, 1944, about 8 weeks after the onset of edema of the face and neck. One month before the onset of these complaints all the teeth had been extracted. The extractions were followed by severe infection of the sockets, lasting for 1 week. Three weeks later edema of the neck, face and breasts developed, spreading to the back, chest and lower extremities. The upper extremities were never involved. The edema was unsightly but not discomforting. The patient was otherwise in good health.

Physical examination revealed edema of the face, conjunctivas, trunk, abdomen and lower extremities. The edema was remarkable in that it was firm and pale and did not pit on pressure. It was not dependent in location and had no relation to gravity, and there was no change in the course of the day. The edema was most marked about the face, especially the forehead, and was present to a moderate degree over the areas previously enumerated. There were marked chemosis and considerable lacrimation. The heart and lungs were not remarkable. The blood pressure was 110/90. A soft liver edge was felt approximately 1 cm below the costal margin. Neurologic examination was not remarkable.

Repeated urine examinations showed no protein or formed elements. The hemoglobin was 85 per cent (Sahli) and the white-cell count 4900, with a normal differential count. The erythrocyte sedimentation rate was 72 minutes. The venous pressure was 7 cm, and the circulation time (decholin) was 17 seconds. The basal metabolic rate was -6, -9 and -3 per cent. Repeated stool examinations revealed no parasites or occult blood. Phenolsulfonphthalein tests on two occasions showed 35 and 25 per cent excretion in 1 hour. The concentration test showed a maximal specific gravity of 1.030. A galactose-tolerance test showed an excretion of 0.85 gm. An oral hippuric acid test revealed an excretion of 3.8 gm. The initial total protein was 6.0 gm per 100 cc, and subsequent determinations were within normal limits. The albumin was 3.7 gm, the globulin 2.3 gm, the phosphorus 4 mg, the calcium 10 mg, the chloride 640 mg, and the cholesterol 300 mg per 100 cc. A bromsulfalein test showed no significant retention.

X-ray examination of the chest revealed an effusion occupying the lower portion of each pleural cavity. The size of the heart could not be determined. A flat plate of the abdomen showed general density, suggesting fluid. A number of electrocardiographic tracings revealed a regular sinus rhythm, with QRS complexes and T waves of extremely low voltage. A skin test for trichinosis was negative.

During the first 3 weeks in the hospital, the urinary output was high, but there was a gain in weight from 165 to 173 pounds. The patient was given injections of Mercupurin, which were effective in producing loss of weight. Nevertheless she remained quite edematous and 15 pounds above her usual weight. Desiccated thyroid was given in large doses, without result, although the basal metabolic rate rose to +9 per cent. Large amounts of human plasma were finally administered without significant effect. The patient was discharged essentially unimproved after 3 months of hospitalization, to return 3 months later for further study. During the interim the edema remained constant. She was readmitted on October 5, 1944.

Physical examination on readmission showed marked edema of the eyelids and conjunctivas. The skin over the previously mentioned areas was edematous and hard, although mostly over the breasts and back. It could not be lifted from the underlying structures, although there was no atrophy or pigmentation. There were many striae but no scarring over

the back and abdomen. The lungs and heart were not remarkable. The blood pressure was 110/70. The hemoglobin was 72 per cent (Sahli) and the white-cell count 5700, with a normal differential count. Urine examinations were always normal. The blood urea nitrogen was 17 mg per 100 cc, the total protein 6 gm, with an albumin of 5.9 gm and a globulin of 1.9 gm, the phosphorus 3 mg, the calcium 10.9 mg, the cholesterol 240 mg, the sodium 143.2 milliequiv per liter, the chloride 104.2 milliequiv, and the uric acid 3.6 mg per 100 cc. A blood Wassermann test was negative. The antifibrinolytic titer was zero. The Aschheim-Zondek test was negative. The visual fields were within normal limits. The basal metabolic rate was -2 per cent. Repeated Sulzowitch tests on the urine gave reactions within normal limits. Skin sensitivity to ultraviolet light was normal. Hippuric acid, phenolsulfonphthalein and cephalin-flocculation tests were negative. A creatinine-tolerance test was negative. Calcium excretion of a 3-day urine specimen of 2635 cc following a Bauer-Aub diet showed 230 mg calcium excretion, which is normal. A salt tolerance test was negative. Two 17-ketosteroid determinations were 12.0 and 16.6 mg per 100 cc, respectively, which are normal. The blood-iodine level was 5 gamma, which is normal. The sedimentation rate of erythrocytes was repeatedly normal.

X-ray examination of the chest showed enlargement of the cardiac shadow to the right and left. There was an enlargement of the right border with markedly diminished pulsation by fluoroscopy and kymography, suggesting a localized pericardial effusion. Right and left pleural effusions that had previously been present had disappeared. Examination of the long bones showed no abnormality. Examination of the sella turcica was negative. Electrocardiographic tracings showed a regular sinus rhythm, left-axis deviation and QRS of low voltage, changes seen in pericardial effusion.

A biopsy of the skin of the right breast showed changes compatible with the diagnosis of scleroderma adultorum. Staining with Kresley's toluidine blue, however, did not reveal an intercollagenous substance.

The patient's course was uneventful except for purulent conjunctivitis, the etiology of which was not discovered. Shitlump examination of the cornea revealed no abnormality. The temperature was normal throughout. There was both subjective and objective improvement. She was treated with effervescent urea, from which she had a good diuresis, but after 2 weeks of its use she became refractory to it and her weight became stabilized at 134 pounds. Because of previously reported pituitary disturbances in scleroderma adultorum,^{12, 25, 33, 35} anterior-pituitary extract (Ambionone) was given every 2nd day in 1-cc doses. The weight subsequently fell from 134 to 128 pounds, while the fluid intake remained restricted throughout. The skin softened noticeably, and the patient was discharged at her own request. The injections were continued three times weekly for 3 months following discharge.

When the patient was last seen in July, 1945, all the skin lesions had disappeared, x-ray examination of the chest was negative, and save for some residual chemosis there was no evidence of the previous disorder.

CASE 4 (M S H 535256) The patient, a 33-year-old woman, was first admitted on June 4, 1945. She had been well until the summer of 1943, when she developed generalized, hard, hrawny edema of the neck, face, abdominal wall, vulva, thighs and legs but not of the upper extremities and chest. A biopsy specimen was taken from the buttocks and was reported as scleroderma. The urine was said to contain formed elements and erythrocytes on several occasions during the early stages of her illness, but subsequently all examinations were negative and renal function was normal throughout. Bilateral pleural effusions developed and required continuous tapping for more than 9 months. Oliguria was an outstanding symptom. There was no cardiovascular disease. The patient was seen by various consultants in different hospitals over the course of 2 years, but no definite diagnosis could be arrived at. The blood chemical values, particularly the total protein, albumin and globulin determinations, were within normal limits at all times. The patient was given all types of available diuretics, without any therapeutic success. Among other measures autotransfusion with pleural fluid and renal decapsulation were performed without benefit. The generalized edema slowly disappeared over the course of months, although the patient was left with residual hrawny edema of the face, conjunctivas, eyelids and

eredema syndrome. Such intrathoracic effusions believe to be intrinsic features of the disease. This indicates, as do the reported hydrarthroses, that scleredema is not limited to the skin and subcutaneous tissue and may in fact present a puzzling picture to the internist.

INCIDENCE

In 1937, Touraine, Golé and Soulignac⁷⁰ were able to collect 70 cases from the literature. We have found a total of 99 reported cases and add 4 of our own, bringing the total to 103. In 97 cases in which knowledge of the sex is available, the patients were men in 33 and women in 64, an incidence of almost two to one in favor of women. An identical ratio reported by Touraine et al.⁷⁰ The greatest age incidence is in childhood and early adult life, as shown in Table 1. The oldest patient reported was

TABLE 1 Age Incidence

51-60	3
61 and over	3

sixty-eight years old.³⁰ The disease has also been observed in the early neonatal period.¹¹

PATHOLOGY

The squamous-cell and keratin layers of the epidermis present no abnormalities. The basal-cell layer may be alternately flattened out or heaped up. The superficial layers of the cutis usually show no feature other than slight perivascular infiltration.¹² Epstein³⁶ noted a band of connective tissue underlying the epidermis. The infiltrating cells are usually fibroblasts, lymphocytes and plasma cells.

The characteristic pathologic features are found in the deeper layers of the cutis.¹² The perivascular infiltration is more pronounced here, although it is variable and may not be at all striking. The collagen bundles are thickened to several times their usual diameter and form a firm fibrous band. Separating the collagen bundles and in interstitial areas throughout the cutis and subcutis are clear areas. There are also areas of fenestration about the blood vessels and hair follicles. With haematoxylin-eosin stain these areas appear empty. Freund¹² used *Kresylechtviolett*, which stained the tissues blue-gray but the material in these clear spaces a brilliant red. He also demonstrated small patches of this amorphous material in islands throughout the entire cutis. Both Voss²⁸ and O'Leary,⁵⁷ however, were unable to stain the interstitial material with *Kresylechtviolett*. This dye in one of our cases also failed to stain the clear areas, and in another case it was

only partially satisfactory. This apparent discrepancy is explained by the fact that the microscopic picture is variable. It probably varies with the stage of the disease, as noted by Epstein,³⁶ and may vary in different areas, retaining, however, the three major characteristics of perivascular infiltration, swelling of the collagen bundles and the presence of areas of fenestration.

The only autopsied case is that of Stenbeck.⁶⁵ He describes proliferation of connective tissue throughout the entire body, leading eventually to death through strangulation of the bowel. This patient, however, presented many unusual features, and the case cannot be accepted as an established one of scleredema.

ETIOLOGY

Buschke¹ was vague about the etiology in his first case. He suggested that the initial infection injured the lymph channels, producing elephantiasis of the skin. That the initial infection produces the agent responsible for the disease is the opinion of many contributors. Credence is lent to this thesis by the fact that the initiating infection is most frequently streptococcal in nature (Table 2). In

TABLE 2 Preceding Infections

No preceding infection	5

addition, in a number of cases the area of scleredema began in the region of the skin injured by the infection.²² 27 30 32 Guv⁴⁵ noted in 1 case that skin sensitivity tests for streptococci were markedly positive.

There is some evidence pointing to the endocrine organs as possible causative factors. No persistent changes in the basal metabolic rate have been described, but in a few cases x-ray evidence of tumor of the pituitary was evident.¹² 25 53 65 In one of these cases, which showed enlargement of the pituitary bed and destruction of the posterior clinoid processes, Schreus²⁵ claims to have experimentally demonstrated a substance in the blood and urine having the same effect on water metabolism as does the extract of the posterior pituitary gland. Selye⁷⁶

the scleredema frequently begins in that area, which has been affected by the previous febrile illness. It is a characteristic feature of the disease that the hands and feet are spared.

The skin is not the only system affected. Cases 3 and 4 showed hydrothorax, and hydrarthrosis was found by Voss,²⁸ Schnitzer,⁶³ and O'Leary.⁵⁷ The patient's complaints usually relate either to the facial edema or to the immobility of the skin. Not infrequently the stiffening of the skin of the thorax restricts chest motion,²³ producing a sensation of dyspnea. Occasionally movements of the extremi-

Except in a few cases in which the initiating febrile illness was nephritis,^{13, 19, 45, 52, 63} the urine consistently shows no abnormality. The total urinary output has not often been recorded, but Buschke⁹ noted that during the edematous phase there was oliguria, with regression of the edema he observed marked diuresis.

The blood is usually within normal limits, showing neither anemia nor leukocytosis. The sedimentation rate is normal or at best slightly elevated.

The basal metabolic rate has been reported as being high⁶¹⁻⁶³ and as being low.⁴⁵ In most cases,

FIGURE 2 Roentgenograms in Case 3

A — This film was taken on admission in April, 1944. B — This film was taken during second admission and shows disappearance of the pleural effusion but persistence of the pericardial effusion, particularly prominent at the right pericardial border. C — This film was taken in June, 1945, when the resolution of the cutaneous manifestations was virtually complete. The patient never had clinical symptoms referable to intrathoracic effusions.

ties are hampered. The maximal area of skin involvement is reached early in the disease, and the course thereafter is one of slow regression. Regression usually begins in the areas last affected and persists longest in those first involved, particularly the neck, face and scalp. Complete resolution has occurred in few cases in less than a month.^{17, 29} In most cases regression takes longer than six months, and not infrequently islands of scleredema are left, slowly resolving after a period of years. It is frequently stated that the disease is self-limited, but the case reported by Adler² showed evidence of scleredema of the eyelids after twenty years. In the case described by Hoffmann,¹⁵ extensive edema persisted for fifteen years. The prognosis for life and function is excellent, and ultimate complete recovery can be expected, yet the duration of the edema is unpredictable.

In a number of cases relapses have occurred.^{2, 3, 36, 57} These characteristically occur after a long free period, — thirteen years in Epstein's³⁶ patients and twenty years in one of O'Leary's.⁵⁷

however, it is in the normal range, as in the present series.

In these cases the total protein, albumin, globulin, chloride, glucose-tolerance, blood-sugar, calcium and phosphorus levels were normal. The 17-ketosteroid excretion in Case 3 was normal, as was the blood-iodine level. No significant blood chemical aberrations have been noted by other authors.^{17, 43, 57, 60, 63}

Electrocardiograms showed QRS complexes of low voltage.

X-ray examination of the chest has only rarely been included in clinical reports but usually shows no abnormality. Nevertheless, the patient in Case 3 had a right pleural effusion when first seen and later developed a loculated effusion along the right border of the heart. Both these effusions regressed as the process cleared up. In Case 4, there were massive bilateral pleural effusions during the initial phase of the disease (Fig 2). To our knowledge, these are the first cases in which pleural and pericardial effusions have been reported as part of the

thinks that topical application of estrogens in mice produces a pathologic picture resembling that of scleredema

Helfand,⁴⁶ struck by the clinical resemblance between trophedema and scleredema, suggested that the pathogenesis might be disease of the peripheral nerves. He demonstrated with Spielmeyer and Weigert-Pal stains disintegration of the myelin sheaths of the subcutaneous nerve fibers.

At present, however, there is insufficient material available to permit a reasonable opinion of the etiology.

DIFFERENTIAL DIAGNOSIS

There are few cases of scleredema that have not at one time been diagnosed as scleroderma, but the differentiation may be easily made on clinical grounds. The hands, so frequently diseased in scleroderma, are spared in scleredema. The skin similarly does not show the atrophy and contractions or areas of pigmentation and depigmentation seen in scleroderma. Whereas scleroderma frequently produces disease of the lungs, esophagus and heart and decalcification of the bones, these changes are never seen in scleredema. Finally, scleredema is a benign and self-limited disease and is usually seen in the stage of regression.

Myxedema may be differentiated by means of the basal metabolic rate, the blood cholesterol values, the general appearance and behavior of the patient and finally the lack of response to desiccated thyroid.

Dermatomyositis occasionally gives rise to a difficult diagnostic problem. Touraine et al.⁷⁰⁻⁷² claim that a number of cases described as acute dermatomyositis are actually scleredema. Nevertheless the presence of muscle pain, fever, a high sedimentation rate and the widespread erythematous skin lesions occasionally seen in dermatomyositis and the weakness and atrophy that are constant features of the disease are not seen in scleredema. Finally, dermatomyositis is usually a progressive and crippling disease. Recovery, which is not frequent, is attended by atrophy and incapacity.

Trichinosis may be ruled out on the basis of the elevation of temperature, the marked muscle tenderness, eosinophilia and the localization and nature of the edema. The skin and complement-fixation tests serve as laboratory aids in the differential diagnosis.

Edema from cardiac and renal as well as hepatic disease is readily differentiated by simple clinical grounds.

TREATMENT

The treatment of the disease is unsatisfactory. The disease appears to follow its own course, unaffected by any therapeutic agents. Our therapeutic trials included desiccated thyroid, dihydro-

tachysterol and anterior pituitary extract. These agents did not contribute markedly to the patient's recovery. O'Leary⁸⁷ claims beneficial results from fever therapy, but his results with it, as well as our own, are not striking. It is also doubtful whether eradication of a focus of infection can be expected to influence the course of the disease. Further studies of the pathogenesis of the process may elucidate the therapeutic problem.

DISCUSSION

The name "scleredema adultorum," as given by Buschke,¹ does not seem appropriate. The term implies that this is an illness seen only in adults, yet the statistics on age distribution (Table I) show that it is most frequently observed in children and adolescents, who account for 50 per cent of all cases on record. Calling the disease "scleredema" without reference to the age groups affected seems more in keeping with the statistical facts.

The recognition of the disease is important because of the excellent prognosis for function and life. The process always undergoes spontaneous regression, in contrast to scleroderma and dermatomyositis, with which it is frequently confused. The pleural effusions in 2 of our cases and the electrocardiographic changes are of interest, particularly since the intrathoracic effusions receded simultaneously with improvement of the cutaneous changes.

Cases of scleredema undoubtedly come under the observation of internists. A relatively small number of cases have been reported in the literature to date. Nevertheless, we have observed and followed 4 cases ourselves within a relatively short period. It seems to be a reasonable conclusion that the disease is not so infrequent as might be suspected.

Any case presenting obscure forms of edema should be suspected, and a detailed history may aid in ascertaining its true cause.

SUMMARY

Scleredema was first described by Buschke. Since his original description 99 cases have appeared in the literature, to which we add 4.

The disease is characterized by firm, nonpitting edema, affecting usually the face, neck, scalp, conjunctivas, thorax, occasionally the arms and more rarely the legs, sparing the hands and feet. Pleural effusions, pericardial effusions and hydrarthroses also occur. The pericardial effusions may be localized. The electrocardiogram shows low voltage of the QRS complexes.

Complete recovery can be expected over a period varying from several months to many years.

Young people are affected more frequently than those in the older age groups. Women are affected twice as often as men.

25 Shattuck Street

Muscle tenderness was present in all the cases with bulbar involvement and in 6 of those without it, total of 16 cases. The muscle groups in which tenderness was found, in the order of frequency, were the hamstring muscles, the posterior calf muscles, the quadriceps muscles and the biceps muscles. It was interesting that tenderness of the muscles of the upper extremities was found in only 3 cases, although paralysis of the upper extremities occurred in 9 patients. One of the 2 patients without muscle tenderness was admitted three and a half weeks after the onset of his illness, and the other showed only involvement of the upper extremities, primarily the abductor muscles of the shoulders. It was also of interest that many more patients showed muscle tenderness than complained of muscle soreness. The tenderness persisted from a few days to weeks.

Fever was present in all cases but 1, which was that of the patient who entered the hospital late in the course of his disease. The height and length of the fever was variable. The temperatures generally ran from 100 to 103°F, but in 3 of the bulbar-involvement cases it was 104°F. Death occurred in 2 of these. So long as the temperature remains elevated, one cannot be certain how much more progression of the disease process there will be. In the bulbar-involvement cases this factor was of prognostic significance.

Muscle spasm was seen in no case with the patient at complete rest. There was no attempt to study muscle spasm by means of the electromyograph or by chronaxie measurements, so that any evidence of muscle spasm was that judged on a purely clinical basis. When certain muscles were placed on stretch, pain and spasm were generally elicited, their principal locations being the neck, back, hamstring muscles and posterior calf muscles. They were not, however, always elicited in paralyzed muscles. In the cases in which the tibialis anticus muscle and the abductor muscles of the shoulder were involved, passive stretching produced neither spasm nor pain. As pointed out by Moldaver,¹ muscle spasm in anterior poliomyelitis is a complex phenomenon, the result of a combination of factors — namely, a normal stretch reflex, meningeal irritation of the posterior roots, an increase of normal tonus in healthy and strong muscles or muscular fibers opposed to weak or paralyzed muscles, and lesions of the dorsal-root ganglions and posterior horns.

Reflex changes were not listed because of their variability and changeability. In most cases with complete muscle paralysis deep reflexes were absent in the involved area, but 1 of the cases with extensive paralysis showed hyperactive deep reflexes throughout. In another case with fairly extensive involvement there were no reflex changes. The reflexes in the same patient often varied from day to day. This was particularly true in the patients with muscle tenderness and weakness but no residual

paralysis. As the muscle tenderness disappeared and strength returned, the reflexes became normal. No pathologic reflexes were obtained. There was no evidence of cortical involvement in any patient.

Sensory changes were elicited in only 1 patient. A summary of this case is given below.

The spinal-fluid findings are listed in Table 3. Only the cell counts and total proteins are recorded. Sugar determinations and Wassermann reactions

are omitted, since the former were either within normal limits or slightly elevated and all the latter were negative. The day of withdrawal of the spinal fluid and its examination is recorded in terms of the onset of the disease.

Repeat spinal-fluid examinations were done in all cases in which the first examination revealed a normal cell count. In 7 cases with bulbar involvement, the spinal fluid obtained on admission showed a normal cell count or one below 10. In the group without bulbar involvement, the initial spinal fluid was normal in 3. One of these patients, however, was admitted late in the course of his illness, and since normal cell counts are not unusual at that time, it was believed that this case should be omitted in the calculation of the percentage. The remaining spinal fluids were obtained from patients in the first week of their illness. Thus, 53 per cent of the spinal fluids obtained on admission showed essentially normal counts — in 7 of the cases with bulbar involvement

SOME UNUSUAL FINDINGS IN AN EPIDEMIC OF ANTERIOR POLIOMYELITIS*

MAJOR JOSEPH H. NICHOLSON, M C, A U S

DURING the months of March and April, 1945, a southern army post experienced a short but explosive outbreak of anterior poliomyelitis. Within a period of twenty-five days, 18 patients suffering from poliomyelitis were admitted to the hospital. There were 3 other cases that were considered to be preparalytic in type, but since the diagnosis was questionable, they are omitted from this discussion.

Anterior poliomyelitis is usually a disease of late summer and early fall. Winter epidemics have been described, but this outbreak cannot be so classified. The weather was unusually warm for the time of year, even though it is taken into consideration that the camp is situated in the southern part of the country, indeed, the temperatures approached those occurring in the summertime.

The diagnosis of acute poliomyelitis was confirmed by pathological studies, autopsies being performed in the 3 fatal cases. Histologic sections of the spinal cord and medulla revealed lesions characteristic of anterior poliomyelitis. Also, poliomyelitic virus was recovered from the central nervous system of 1 of the patients.*

All the cases occurred in soldiers, whose ages ranged from eighteen to thirty-three years, all but 3 were between eighteen and twenty-one years old. This camp has approximately 30,000 troops, most of whom are recruits, largely infantrymen. Some of those who contracted the disease lived outside the camp, although the great majority were stationed on the post. The post is located four miles from a city with a population of 40,000, and traffic between the camp and city is extensive. In spite of this, no cases occurred in any of the civilian population. It is not the purpose of this paper to discuss any epidemiologic aspect of this outbreak, but it should be stated that there was no personal contact between any of the patients.

The patients afflicted with the disease in this epidemic showed some unusual findings. There were 10 (55 per cent) with bulbar involvement. There were 3 deaths, all in cases with bulbar involvement and all caused by failure of the respiratory center. Also of considerable interest were some unusual spinal-fluid findings. This subject is discussed in detail below.

In Table 1 are detailed the symptoms and their frequency of occurrence. As can be seen, headache was the symptom most commonly noted, but in no case was it severe or marked, nor was it the chief complaint in any case. In a few cases direct questioning was necessary to elicit this symptom. Muscle pain, backache and dysphagia were the next most

frequent symptoms. The muscle pain was described in the majority of cases as "soreness" or "aches," and in some cases as an acute, severe pain. There were no shooting pains, such as those experienced in radiculitis. Dysphagia varied in intensity. Some patients were completely unable to swallow, others were able to swallow small amounts of liquids and

TABLE 1 Symptoms

soft, mushy foods, generally washed down with liquids. Those who were able to swallow liquids tired easily, and it required an appreciable effort for them to swallow. The listing of stiffness of the neck as a symptom refers to subjective stiffness as reported by the patients, not to objective findings of stiffness, which were much more frequent (Table 2).

The physical findings have been divided into two groups, those in cases with bulbar involvement and those without it. Cranial nerves were affected in all

TABLE 2 Physical Findings

bulbar cases, and paralysis of the extremities occurred in certain cases of both groups. The latter was generally mild. Of the cases with bulbar involvement, 5 showed no evidence of actual paralysis, but in 4 of these there was peripheral muscle weakness. The patient who showed no evidence of cord involvement died within a week after the onset of his illness.

*This work was done by the Commission on Neurotropic Virus Diseases, Office of the Surgeon General, United States Army.

ients with bulbar involvement who survived were able to swallow after a period of two weeks, but 5 of them had some residual. Two had slight dysphagia. Of these, one had a mild facial paralysis and the other a slight involvement of the sternomastoid muscle on one side. The 3 remaining patients had paralysis of the peripheral muscles. Of the 8 patients without bulbar involvement, 7 had some residual peripheral paralysis, although in each case improvement occurred. In 1 case there was complete recovery.

DISCUSSION

A short but violent outbreak of poliomyelitis occurring in adults has been presented. Poliomyelitis is primarily a disease of childhood. There has, however, been a gradual shift toward older age groups in poliomyelitis in both rural and urban populations in the last twenty years.⁵

This particular epidemic was characterized by a high incidence of bulbar-involvement cases. Stebbins et al.⁶ reported on an outbreak of 20 cases, 13 of which were of the bulbar type, 12 of these terminated fatally. The incidence of bulbar involvement varies with different epidemics. Lemmon,⁷ in an analysis of 49 cases occurring in an epidemic in Pennsylvania, reports an incidence of bulbar involvement of 12 per cent. Fischer et al.⁸ also report an incidence of 12 per cent, in a Toronto epidemic. Generally speaking, the incidence of bulbar involvement varies between 5 and 10 per cent.

The relation between tonsillectomy and bulbar poliomyelitis has been definitely established. None of the patients with bulbar involvement in this series had had a recent tonsillectomy and the proportion of those patients who had had tonsillectomy in the past was no greater than that of those without it.

Of considerable interest was the large proportion of patients with no increase in cells in the cerebrospinal fluid. On the initial examination 53 per cent of the spinal fluids showed normal cell counts. It had been noted that the usual findings in the cerebrospinal fluid in cases of anterior poliomyelitis are an increase in cell count and a slightly elevated protein during the first week, with a gradual decrease in cells to the third week and with a gradual increase in total protein.⁹ Cases without an increase in the cell count, however, have been reported,¹⁰⁻¹² and the incidence of cases without cellular response in the spinal fluid has been estimated at 12 per cent.¹¹ In the Los Angeles epidemic of 1934, approximately 33 per cent of the patients had normal cell counts.¹² Similarly, Jensen¹³ has reported 36 per cent of 3340 cases occurring in Denmark with normal cell counts.

Of particular interest is the case discussed above. The albuminocytologic disassociation is obvious. As is well known, this is a cardinal finding in the Guillain-Barré syndrome (infectious polyn neuritis). It will also be noted that in Cases 3, 5 and 9 this disassociation was also present. Cases of infectious

polyn neuritis occurring during poliomyelitis epidemics have been reported.¹⁴ An autopsy performed in Case 3, however, revealed the typical pathologic findings of poliomyelitis.

These observations demonstrate the difficulties encountered in the differential diagnosis of poliomyelitis and the Guillain-Barré syndrome. Different clinical criteria have been mentioned in numerous publications, they concern the mode of onset, the distribution of the paralyses and the laboratory findings. Progressive paralysis with diffuse symmetrical involvement, involvement of the facial nerve and albuminocytologic disassociation have been brought forth as differentiating the Guillain-Barré syndrome from poliomyelitis. The usually favorable outcome has also been pointed out as a differentiating point. Recent statistics, however, show the occurrence of a high mortality rate in polyn neuritis.¹⁵ On the other hand, complete recovery following an attack of poliomyelitis is frequently observed. It will be noted in the case reported above that many of the features of the Guillain-Barré syndrome were present. The course of the disease, however, was not that usually seen in this syndrome. Jervis et al.¹⁶ reported a case in which the clinical manifestations and laboratory findings that are considered typical of the Guillain-Barré syndrome were seen and in which autopsy indicated acute poliomyelitis. They believe that differentiation based on clinical symptoms, observations of the spinal fluid and the final outcome is open to question and that this raises the problem whether the two diseases are distinct entities or different clinical manifestations of the same agent. The point can only be settled from an etiologic point of view by isolating the poliomyelitis virus or another virus from patients with infectious polyn neuritis.

SUMMARY

The symptoms and physical and spinal-fluid findings in a short but explosive epidemic of anterior poliomyelitis are described.

An unusually high percentage of cases with bulbar involvement occurred.

A large percentage of the cases failed to show the cellular response usually seen in the spinal fluid in poliomyelitis.

The albuminocytologic disassociation described in the Guillain-Barré syndrome was found in 3 of the 18 cases in this series.

and in 2 of those without it. Of this group of 9 cases there was an elevated total protein in 6, although 2 (Cases 2 and 15) showed only a slight elevation. Repeat spinal-fluid examination in this group done within a few days after the original examination showed an increase in cells in 5 cases. All but 2 showed some abnormality in the cerebrospinal fluid after repeated examinations.

The pathologic process and distribution of the virus in the central nervous system in cases of poliomyelitis are more widespread than the amount of paralysis indicates. All parts of the central nervous system appear to be involved to some extent, but the changes indicative of injury or destruction of nerve cells are generally found in the motor nerve cells of the brain stem and spinal cord. The large, deeply staining anterior-horn cells of the cord seem to be most vulnerable ones.

In the case reported below, there was extensive sensory involvement, as well as motor involvement, and an almost complete transverse myelitis.

CASE 10 A 28-year-old soldier was well until 2 days before admission to the hospital, when he developed general malaise, felt feverish and had generalized muscular aches. The following day he developed dysphagia and noticed a change in the quality of his voice. Attempts to swallow even fluids were followed by regurgitation through the nose. Later on that day he noticed some weakness of the left arm.

Physical examination revealed stiffness of the neck and back, a positive Kernig's sign and weakness of abductor muscles of the left shoulder. There were no reflex or sensory changes. The temperature was 102°F, the pulse 100, and the respirations 22.

For the next 2 days the patient continued to run an elevated temperature with little change in the general picture. He was unable to swallow even liquids and was given 1000 cc of pooled plasma, together with 5 per cent glucose and normal saline solution, up to 3500 cc daily. On the 3rd hospital day he developed complete paralysis of both lower extremities. He was found to have paralysis of the bladder and of the rectal sphincter. There was loss of the abdominal and cremasteric reflexes. The deep reflexes of the lower extremities were absent. There was no plantar reflex on either side. Position sense in the lower extremities was completely lost. There was also diminished tactile sensation corresponding to the level of the 2nd lumbar segment. Pain and temperature sensations were unaffected. There was weakness of the abdominal muscles and the abductor muscles of the left shoulder. Closed drainage of the bladder was instituted.

The patient continued to run an elevated temperature for 6 more days. His condition remained much the same during that period, after which he began to show gradual improvement. On the 12th hospital day he was able to swallow liquids, then soft solid foods. On discharge to an Army medical center for poliomyelitis 6 weeks after admission, he still had paralysis of the bladder, but the tone of the rectal sphincter had improved. There was return in function of the abdominal muscles and many muscle groups of the lower extremities, although there was still fairly extensive involvement. The abductor muscles of the left shoulder were much the same as on admission.

A report from the medical center showed paralysis of the lower extremities involving a diffuse group of muscles. There had been moderate improvement, but there was still considerable involvement of the right gastrocnemius muscle. Bladder paralysis was still present, but function had recovered sufficiently so that the use of a catheter was no longer necessary. The rectal sphincter had returned almost to its normal tone. This report covered the status of the patient 7 months after the onset of his illness.

Approximately 50 per cent of the patients in this series received both pooled plasma and penicillin.

Plasma was given in doses of 500 to 1500 cc. Penicillin was given intramuscularly, with an average total dosage of 1,680,000 units.

The evaluation of any therapeutic measure in anterior poliomyelitis is extremely difficult. In any such appraisal it must be borne in mind that a relation between the severity of the earlier symptoms and the ultimate appearance of the paralysis is inconstant; the death rate and the amount of residual paralysis vary greatly from place to place and in different epidemics. Furthermore, none of our patients were admitted in the preparalytic stage. So far as could be determined, neither plasma nor penicillin had any effect on the course of the disease. Convalescent poliomyelitis serum has been used in preparalytic states of poliomyelitis without benefit,¹ so that it is not surprising that no therapeutic results were obtained with pooled plasma given when paralysis or paresis had already set in. In addition, penicillin is reported to have no effect on the poliomyelitis virus.^{2, 4}

The hot-pack treatment, as advocated by Sister Kenny, was carried out on all but 2 patients. The patients with involvement of the lower extremities were placed on a mattress stiffened by a board placed over the springs and so placed that there was a distance of several centimeters between it and the foot of the bed. The soles of the feet rested against the footboard, and the heels were in the space between it and the mattress. When muscle tenderness and pain cleared, physiotherapy, including baking, massage and passive and active motion, were instituted. There was little doubt that hot packs definitely diminished the muscle soreness and pain. No plaster casts or splints were used. The cases with involvement of the upper extremities showed only moderate or slight paralysis, and pillows were used for support.

For the patients unable to swallow, tube feeding was used, but in the first few days of the illness, when the temperature was elevated and the patient was acutely ill, this was not done, but instead fluids were given parenterally. It was believed that tube feeding during the acute phase caused a marked increase in pharyngeal secretions, requiring constant suction. In no case was tube feeding necessary for longer than two weeks. In 2 of the 3 fatal cases the Drinker respirator was used when the respiratory center became involved. It had no effect on the ultimate outcome, although life was prolonged for about twenty-four hours.

The patients could be followed only for seven weeks. Those who had residual paralysis were transferred to an Army and Navy general hospital for further treatment.

There were 3 deaths, all occurring in bulbar involvement cases, and all from failure of the respiratory center. Thus, there was a 16 per cent mortality in the series as a whole and a 30 per cent mortality in the cases with bulbar involvement. The 7 pa-

ients with bulbar involvement who survived were able to swallow after a period of two weeks but 5 of them had some residual. Two had slight dysphagia. Of these one had a mild facial paralysis and the other a slight involvement of the sternomastoid muscle on one side. The 3 remaining patients had paralysis of the peripheral muscles. Of the 8 patients without bulbar involvement, 7 had some residual peripheral paralysis, although in each case improvement occurred. In 1 case there was complete recovery.

DISCUSSION

A short but violent outbreak of poliomyelitis occurring in adults has been presented. Poliomyelitis is primarily a disease of childhood. There has, however, been a gradual shift toward older age groups in poliomyelitis in both rural and urban populations in the last twenty years.⁵

This particular epidemic was characterized by a high incidence of bulbar-involvement cases. Stebbins et al.⁶ reported on an outbreak of 20 cases, 13 of which were of the bulbar type, 12 of these terminated fatally. The incidence of bulbar involvement varies with different epidemics. Lemmon,⁷ in an analysis of 49 cases occurring in an epidemic in Pennsylvania, reports an incidence of bulbar involvement of 12 per cent. Fischer et al.⁸ also report an incidence of 12 per cent, in a Toronto epidemic. Generally speaking, the incidence of bulbar involvement varies between 5 and 10 per cent.

The relation between tonsillectomy and bulbar poliomyelitis has been definitely established. None of the patients with bulbar involvement in this series had had a recent tonsillectomy and the proportion of those patients who had had tonsillectomy in the past was no greater than that of those without it.

Of considerable interest was the large proportion of patients with no increase in cells in the cerebrospinal fluid. On the initial examination 53 per cent of the spinal fluids showed normal cell counts. It had been noted that the usual findings in the cerebrospinal fluid in cases of anterior poliomyelitis are an increase in cell count and a slightly elevated protein during the first week with a gradual decrease in cells to the third week and with a gradual increase in total protein.⁹ Cases without an increase in the cell count, however, have been reported,¹⁰⁻¹³ and the incidence of cases without cellular response in the spinal fluid has been estimated at 12 per cent.¹¹ In the Los Angeles epidemic of 1934, approximately 33 per cent of the patients had normal cell counts.¹² Similarly, Jensen¹³ has reported 36 per cent of 3340 cases occurring in Denmark with normal cell counts.

Of particular interest is the case discussed above. The albuminocytologic disassociation is obvious. As is well known, this is a cardinal finding in the Guillain-Barré syndrome (infectious polyneuritis). It will also be noted that in Cases 3, 5 and 9 this disassociation was also present. Cases of infectious

polyneuritis occurring during poliomyelitis epidemics have been reported.¹⁴ An autopsy performed in Case 3, however, revealed the typical pathologic findings of poliomyelitis.

These observations demonstrate the difficulties encountered in the differential diagnosis of poliomyelitis and the Guillain-Barré syndrome. Different clinical criteria have been mentioned in numerous publications, they concern the mode of onset, the distribution of the paralyses and the laboratory findings. Progressive paralysis with diffuse symmetrical involvement, involvement of the facial nerve and albuminocytologic disassociation have been brought forth as differentiating the Guillain-Barré syndrome from poliomyelitis. The usually favorable outcome has also been pointed out as a differentiating point. Recent statistics, however, show the occurrence of a high mortality rate in polyneuritis.¹⁵ On the other hand, complete recovery following an attack of poliomyelitis is frequently observed. It will be noted in the case reported above that many of the features of the Guillain-Barré syndrome were present. The course of the disease, however, was not that usually seen in this syndrome. Jervis et al.¹⁶ reported a case in which the clinical manifestations and laboratory findings that are considered typical of the Guillain-Barré syndrome were seen and in which autopsy indicated acute poliomyelitis. They believe that differentiation based on clinical symptoms, observations of the spinal fluid and the final outcome is open to question and that this raises the problem whether the two diseases are distinct entities or different clinical manifestations of the same agent. The point can only be settled from an etiologic point of view by isolating the poliomyelitis virus or another virus from patients with infectious polyneuritis.

SUMMARY

The symptoms and physical and spinal-fluid findings in a short but explosive epidemic of anterior poliomyelitis are described.

An unusually high percentage of cases with bulbar involvement occurred.

A large percentage of the cases failed to show the cellular response usually seen in the spinal fluid in poliomyelitis.

The albuminocytologic disassociation described in the Guillain-Barré syndrome was found in 3 of the 18 cases in this series.

and in 2 of those without it. Of this group of 9 cases there was an elevated total protein in 6, although 2 (Cases 2 and 15) showed only a slight elevation. Repeat spinal-fluid examination in this group done within a few days after the original examination showed an increase in cells in 5 cases. All but 2 showed some abnormality in the cerebrospinal fluid after repeated examinations.

The pathologic process and distribution of the virus in the central nervous system in cases of poliomyelitis are more widespread than the amount of paralysis indicates. All parts of the central nervous system appear to be involved to some extent, but the changes indicative of injury or destruction of nerve cells are generally found in the motor nerve cells of the brain stem and spinal cord. The large, deeply staining anterior-horn cells of the cord seem to be most vulnerable ones.

In the case reported below, there was extensive sensory involvement, as well as motor involvement, and an almost complete transverse myelitis.

CASE 10 A 28-year-old soldier was well until 2 days before admission to the hospital, when he developed general malaise, felt feverish and had generalized muscular aches. The following day he developed dysphagia and noticed a change in the quality of his voice. Attempts to swallow even fluids were followed by regurgitation through the nose. Later on that day he noticed some weakness of the left arm. Physical examination revealed stiffness of the neck and back, a positive Kernig's sign and weakness of abductor muscles of the left shoulder. There were no reflex or sensory changes. The temperature was 102°F, the pulse 100, and the respirations 22.

For the next 2 days the patient continued to run an elevated temperature with little change in the general picture. He was unable to swallow even liquids and was given 1000 cc of pooled plasma, together with 5 per cent glucose and normal saline solution, up to 3500 cc daily. On the 3rd hospital day he developed complete paralysis of both lower extremities. He was found to have paralysis of the bladder and of the rectal sphincter. There was loss of the abdominal and cremasteric reflexes. The deep reflexes of the lower extremities were absent. There was no plantar reflex on either side. Position sense in the lower extremities was completely lost. There was also diminished tactile sensation corresponding to the level of the 2nd lumbar segment. Pain and temperature sensations were unaffected. There was weakness of the abdominal muscles and the abductor muscles of the left shoulder. Closed drainage of the bladder was instituted.

The patient continued to run an elevated temperature for 6 more days. His condition remained much the same during that period, after which he began to show gradual improvement. On the 12th hospital day he was able to swallow liquids, then soft solid foods. On discharge to an Army medical center for poliomyelitis 6 weeks after admission, he still had paralysis of the bladder, but the tone of the rectal sphincter had improved. There was return in function of the abdominal muscles and many muscle groups of the lower extremities, although there was still fairly extensive involvement. The abductor muscles of the left shoulder were much the same as on admission.

A report from the medical center showed paralysis of the lower extremities involving a diffuse group of muscles. There had been moderate improvement, but there was still considerable involvement of the right gastrocnemius muscle. Bladder paralysis was still present, but function had recovered sufficiently so that the use of a catheter was no longer necessary. The rectal sphincter had returned almost to its normal tone. This report covered the status of the patient 7 months after the onset of his illness.

Approximately 50 per cent of the patients in this series received both pooled plasma and penicillin.

Plasma was given in doses of 500 to 1500 cc. Penicillin was given intramuscularly, with an average total dosage of 1,680,000 units.

The evaluation of any therapeutic measure in anterior poliomyelitis is extremely difficult. In any such appraisal it must be borne in mind that a relation between the severity of the earlier symptoms and the ultimate appearance of the paralysis is not constant; the death rate and the amount of residual paralysis vary greatly from place to place and in different epidemics. Furthermore, none of our patients were admitted in the preparalytic stage. So far as could be determined, neither plasma nor penicillin had any effect on the course of the disease. Convalescent poliomyelitis serum has been used in preparalytic states of poliomyelitis without benefit,¹ so that it is not surprising that no therapeutic results were obtained with pooled plasma given when paralysis or paresis had already set in. In addition, penicillin is reported to have no effect on the poliomyelitis virus.^{3,4}

The hot-pack treatment, as advocated by Sister Kenny, was carried out on all but 2 patients. The patients with involvement of the lower extremities were placed on a mattress stiffened by a board placed over the springs and so placed that there was a distance of several centimeters between it and the foot of the bed. and in 2 of those without it. Of this group of 9 cases there was an elevated total protein in 6, although 2 (Cases 2 and 15) showed only a slight elevation. Repeat spinal-fluid examination in this group done within a few days after the original examination showed an increase in cells in 5 cases. All but 2 showed some abnormality in the cerebrospinal fluid after repeated examinations.

The pathologic process and distribution of the virus in the central nervous system in cases of poliomyelitis are more widespread than the amount of paralysis indicates. All parts of the central nervous system appear to be involved to some extent, but the changes indicative of injury or destruction of nerve cells are generally found in the motor nerve cells of the brain stem and spinal cord. The large, deeply staining anterior-horn cells of the cord seem to be most vulnerable ones.

In the case reported below, there was extensive sensory involvement, as well as motor involvement, and an almost complete transverse myelitis.

CASE 10 A 28-year-old soldier was well until 2 days before admission to the hospital, when he developed general malaise, felt feverish and had generalized muscular aches. The following day he developed dysphagia and noticed a change in the quality of his voice. Attempts to swallow even fluids were followed by regurgitation through the nose. Later on that day he noticed some weakness of the left arm.

Physical examination revealed stiffness of the neck and back, a positive Kernig's sign and weakness of abductor muscles of the left shoulder. There were no reflex or sensory changes. The temperature was 102°F, the pulse 100, and the respirations 22.

For the next 2 days the patient continued to run an elevated temperature with little change in the general picture. He was unable to swallow even liquids and was given 1000 cc of pooled plasma, together with 5 per cent glucose and normal saline solution, up to 3500 cc daily. On the 3rd hospital day he developed complete paralysis of both lower extremities. He was found to have paralysis of the bladder and of the rectal sphincter. There was loss of the abdominal and cremasteric reflexes. The deep reflexes of the lower extremities were absent. There was no plantar reflex on either side. Position sense in the lower extremities was completely lost. There was also diminished tactile sensation corresponding to the level of the 2nd lumbar segment. Pain and temperature sensations were unaffected. There was weakness of the abdominal muscles and the abductor muscles of the left shoulder. Closed drainage of the bladder was instituted.

The patient continued to run an elevated temperature for 6 more days. His condition remained much the same during that period, after which he began to show gradual improvement. On the 12th hospital day he was able to swallow liquids, then soft solid foods. On discharge to an Army medical center for poliomyelitis 6 weeks after admission, he still had paralysis of the bladder, but the tone of the rectal sphincter had improved. There was return in function of the abdominal muscles and many muscle groups of the lower extremities, although there was still fairly extensive involvement. The abductor muscles of the left shoulder were much the same as on admission.

A report from the medical center showed paralysis of the lower extremities involving a diffuse group of muscles. There had been moderate improvement, but there was still considerable involvement of the right gastrocnemius muscle. Bladder paralysis was still present, but function had recovered sufficiently so that the use of a catheter was no longer necessary. The rectal sphincter had returned almost to its normal tone. This report covered the status of the patient 7 months after the onset of his illness.

Approximately 50 per cent of the patients in this series received both pooled plasma and penicillin.

Plasma was given in doses of 500 to 1500 cc. Penicillin was given intramuscularly, with an average total dosage of 1,680,000 units.

The evaluation of any therapeutic measure in anterior poliomyelitis is extremely difficult. In any such appraisal it must be borne in mind that a relation between the severity of the earlier symptoms and the ultimate appearance of the paralysis is inconstant; the death rate and the amount of residual paralysis vary greatly from place to place and in different epidemics. Furthermore, none of our patients were admitted in the preparalytic stage. So far as could be determined, neither plasma nor penicillin had any effect on the course of the disease. Convalescent poliomyelitis serum has been used in preparalytic states of poliomyelitis without benefit,² so that it is not surprising that no therapeutic results were obtained with pooled plasma given when paralysis or paresis had already set in. In addition, penicillin is reported to have no effect on the poliomyelitis virus.^{3, 4}

The hot-pack treatment, as advocated by Sister Kenny, was carried out on all but 2 patients. The patients with involvement of the lower extremities were placed on a mattress stiffened by a board placed over the springs and so placed that there was a distance of several centimeters between it and the foot of the bed. The soles of the feet rested against the footboard, and the heels were in the space between it and the mattress. When muscle tenderness and pain cleared, physiotherapy, including baking, massage and passive and active motion, were instituted. There was little doubt that hot packs definitely diminished the muscle soreness and pain. No plaster casts or splints were used. The cases with involvement of the upper extremities showed only moderate or slight paralysis, and pillows were used for support.

For the patients unable to swallow, tube feeding was used, but in the first few days of the illness, when the temperature was elevated and the patient was acutely ill, this was not done, but instead fluids were given parenterally. It was believed that tube feeding during the acute phase caused a marked increase in pharyngeal secretions, requiring constant suction. In no case was tube feeding necessary for longer than two weeks. In 2 of the 3 fatal cases the Drinker respirator was used when the respiratory center became involved. It had no effect on the ultimate outcome, although life was prolonged for about twenty-four hours.

The patients could be followed only for seven weeks. Those who had residual paralysis were transferred to an Army and Navy general hospital for further treatment.

There were 3 deaths, all occurring in bulbar-involvement cases, and all from failure of the respiratory center. Thus, there was a 16 per cent mortality in the series as a whole and a 30 per cent mortality in the cases with bulbar involvement. The 7 pa-

tients with bulbar involvement who survived were able to swallow after a period of two weeks, but 5 of them had some residual. Two had slight dysphagia. Of these, one had a mild facial paralysis and the other a slight involvement of the sternomastoid muscle on one side. The 3 remaining patients had paralysis of the peripheral muscles. Of the 8 patients without bulbar involvement, 7 had some residual peripheral paralysis, although in each case improvement occurred. In 1 case there was complete recovery.

DISCUSSION

A short but violent outbreak of poliomyelitis occurring in adults has been presented. Poliomyelitis is primarily a disease of childhood. There has, however, been a gradual shift toward older age groups in poliomyelitis in both rural and urban populations in the last twenty years.⁵

This particular epidemic was characterized by a high incidence of bulbar-involvement cases. Stebbins et al.⁶ reported on an outbreak of 20 cases, 13 of which were of the bulbar type, 12 of these terminated fatally. The incident of bulbar involvement varies with different epidemics. Lemmon,⁷ in an analysis of 49 cases occurring in an epidemic in Pennsylvania, reports an incidence of bulbar involvement of 12 per cent. Fischer et al.⁸ also report an incidence of 12 per cent, in a Toronto epidemic. Generally speaking, the incidence of bulbar involvement varies between 5 and 10 per cent.

The relation between tonsillectomy and bulbar poliomyelitis has been definitely established. None of the patients with bulbar involvement in this series had had a recent tonsillectomy and the proportion of those patients who had had tonsillectomy in the past was no greater than that of those without it.

Of considerable interest was the large proportion of patients with no increase in cells in the cerebrospinal fluid. On the initial examination 53 per cent of the spinal fluids showed normal cell counts. It had been noted that the usual findings in the cerebrospinal fluid in cases of anterior poliomyelitis are an increase in cell count and a slightly elevated protein during the first week, with a gradual decrease in cells to the third week and with a gradual increase in total protein.⁹ Cases without an increase in the cell count, however, have been reported,¹⁰⁻¹³ and the incidence of cases without cellular response in the spinal fluid has been estimated at 12 per cent.¹¹ In the Los Angeles epidemic of 1934, approximately 33 per cent of the patients had normal cell counts.¹² Similarly, Jensen¹³ has reported 36 per cent of 3340 cases occurring in Denmark with normal cell counts.

Of particular interest is the case discussed above. The albuminocytologic disassociation is obvious. As is well known, this is a cardinal finding in the Guillain-Barré syndrome (infectious polyneuritis). It will also be noted that in Cases 3, 5 and 9 this disassociation was also present. Cases of infectious

polyneuritis occurring during poliomyelitis epidemics have been reported.¹⁴ An autopsy performed in Case 3, however, revealed the typical pathologic findings of poliomyelitis.

These observations demonstrate the difficulties encountered in the differential diagnosis of poliomyelitis and the Guillain-Barré syndrome. Different clinical criteria have been mentioned in numerous publications, they concern the mode of onset, the distribution of the paralysis and the laboratory findings. Progressive paralysis with diffuse symmetrical involvement, involvement of the facial nerve and albuminocytologic disassociation have been brought forth as differentiating the Guillain-Barré syndrome from poliomyelitis. The usually favorable outcome has also been pointed out as a differentiating point. Recent statistics, however, show the occurrence of a high mortality rate in polyneuritis.¹⁵ On the other hand, complete recovery following an attack of poliomyelitis is frequently observed. It will be noted in the case reported above that many of the features of the Guillain-Barré syndrome were present. The course of the disease, however, was not that usually seen in this syndrome. Jervis et al.¹⁶ reported a case in which the clinical manifestations and laboratory findings that are considered typical of the Guillain-Barré syndrome were seen and in which autopsy indicated acute poliomyelitis. They believe that differentiation based on clinical symptoms, observations of the spinal fluid and the final outcome is open to question and that this raises the problem whether the two diseases are distinct entities or different clinical manifestations of the same agent. The point can only be settled from an etiologic point of view by isolating the poliomyelitis virus or another virus from patients with infectious polyneuritis.

SUMMARY

The symptoms and physical and spinal-fluid findings in a short but explosive epidemic of anterior poliomyelitis are described.

An unusually high percentage of cases with bulbar involvement occurred.

A large percentage of the cases failed to show the cellular response usually seen in the spinal fluid in poliomyelitis.

The albuminocytologic disassociation described in the Guillain-Barré syndrome was found in 3 of the 18 cases in this series.

TETANUS, WITH DEATH DUE TO ASEPTIC DURAL SINUS THROMBOSIS

Report of a Case

ELBERT T. PHELPS, M.D.*

MANCHESTER, NEW HAMPSHIRE

THE following case of tetanus is reported because of several unusual features, one of which—aseptic dural sinus thrombosis—was apparently the cause of the fatal outcome.

CASE REPORT

P. G., a 6-year-old boy, entered the Elliot Hospital on September 1, 1945, with the chief complaint of difficulty in swallowing of 1 week's duration. Three weeks prior to entry, a wood splinter penetrated deep into the left anterior tibial area. Part of the splinter was removed and the wound was dressed at home. The patient was well until 1 week prior to admission, when a "frozen" expression appeared on his face and he had slight difficulty in swallowing. Four days prior to entry, there were painful muscular contractions at night. On the day of admission difficulty in walking developed.

The family and past histories were noncontributory. The patient had had measles as an infant. He had had no inoculations or immunizations.

Physical examination disclosed a well developed, well nourished and fairly well hydrated boy, who was alert and co-operative but somewhat apprehensive. Skin turgor was good. The skin was tightly drawn over the contracted facial and abdominal muscles. All the muscles were hypertonic and resisted passive motion. The neck was slightly retracted and the back was slightly hyperextended. All deep tendon reflexes were hyperactive. Kernig and Brudzinski reflexes were markedly positive. There was severe pain on attempted flexion of the neck, which was extremely stiff. The Babinski reflex was negative. Trismus and risus sardonicus were present. The mouth could be opened to 1 cm. between the teeth anteriorly. There was a nearly healed, nontender stab wound 3 mm. in diameter on the left anterior tibial area.

The red-cell count was 4,960,000 and the white-cell count 13,800, with 81 per cent adult and 1 per cent young neutrophils, 16 per cent lymphocytes, 1 per cent monocytes and 1 per cent eosinophils. The hemoglobin was 13.9 gm. Blood Hinton and Mazzini tests were negative. The patient was incontinent, and no urinalysis was done on admission. A lumbar puncture was done shortly after entry. The spinal-fluid sugar was 88 mg. per 100 cc., and the protein 18.7 mg. Pandey's reaction was negative, and the gold-sol curve was normal. Culture of the spinal fluid showed no growth.

The wound was excised and sodium perborate dressings were applied. Histologic examination of the excised area showed granulation tissue beneath an intact epidermis. Yellow foreign material, probably of vegetable origin and surrounded by large foreign-body giant cells and chronic inflammatory exudate cells, was seen. Gram stain showed large numbers of gram-positive bacilli, thought to be tetanus bacilli, and gram-positive cocci near the foreign bodies and in the adjacent soft tissue.

A diagnosis of tetanus was made, and treatment was begun shortly after entry. An initial dose of 40,000 units of tetanus

antitoxin was given intramuscularly into the buttocks. Forty five milligrams of Nembutal was given at entry and 33 mg. every 3 hours thereafter. Sodium luminal in doses of 65 mg. was given intramuscularly for acute spasm when needed. The patient was placed in a dark, quiet room. Hydration and dietary status were maintained by a special liquid for mola taken through a straw. The formula was based on whole milk with added Dextrinmaltose, sodium chloride, vitamin B complex and vitamins A, D and C. Other nourishing liquids and water were given by mouth as the patient tolerated them.

On the 2nd day, more frequent and severer painful muscular spasms of a generalized nature began, and the temperature rose to 101.8°F. Swallowing seemed easier. The abdominal and limb muscles were more spastic, and the neck and back more rigid. A dose of 10,000 units of tetanus antitoxin was given intramuscularly and repeated on the 3 following days. On the 3rd day, the patient rested and slept fairly comfortably. He was still incontinent of urine. Muscular rigidity continued to be marked. The rectal temperature varied from 99.8 to 101°F.

During the next 4 days, there was steady improvement. Trismus and muscle spasticity decreased, there were fewer severe muscular contractions, and the patient was able to speak and smile more normally. On the 7th day, however, the patient vomited a small amount of yellow-green material. The vomiting continued despite sedation and on the 8th day became projectile. All oral medications were vomited, and the patient became extremely restless. The temperature had risen to 104.6°F, the pulse to 136, and the respirations to 36. One thousand cubic centimeters of normal saline solution was given by clysis. Later in the day the rectal temperature rose to 106.6°F. Penicillin in doses of 10,000 units every 3 hours was given intramuscularly.

On the 9th day, a surgical consultant examined the patient because of abdominal pain and moderate distention, but believed that there was no intra-abdominal disease. Later in the day the temperature dropped to 102.6°F. The pulse was 128, and the respirations 30. Projectile vomiting continued and became more violent. The red-cell count was 6,380,000 and the white-cell count 15,400, with a moderate shift to the left in neutrophils—probable evidence of hemoconcentration and dehydration, a factor to be considered in the light of vomiting and perspiration. The hemoglobin was 15.3 gm.

On the 10th day, oxygen was started. Blood examination showed correction of the hemoconcentration. The red-cell count was 4,760,000. Urinalysis showed many hyaline and granular casts but was otherwise negative. A second lumbar puncture was performed. The dynamics of the spinal fluid could not be ascertained because of difficulty in controlling the patient. The fluid contained 26 red cells and 1 lymphocyte per cubic millimeter. Pandey's reaction was negative. No organisms were seen in the smear of the fluid. The protein was 25 mg. per 100 cc. Culture showed no growth.

Projectile vomiting continued, and terminally the vomitus contained a large amount of greenish-black material of foul

*Formerly, resident, Elliot Hospital, Manchester, New Hampshire.

odor, which was partly aspirated into the lungs. Artificial respiration and dependent drainage were of no avail, and the patient expired.

Autopsy (performed by Dr S M Brooks) The body was that of a moderately emaciated child. There was a healing scar at the site of the excision of the original infection. The bronchi contained green-brown gastric material, and there were a few areas of red-brown mottling on the cut surfaces of the lungs. The stomach was somewhat dilated and contained thick, greenish-brown fluid. The urinary bladder was empty.

The dura of the brain was of normal thickness and appearance and was not adherent to the calvarium. The right lateral sinus contained an ante-mortem thrombus extending into the superior sagittal sinus and the jugular vein. The thrombus was not adherent to the walls of the sinus and the intimal lining of the sinus appeared smooth and glistening. The cerebral vessels were not remarkable. The convolutions of the brain were slightly flattened, and there was slight narrowing of the sulci. The brain weighed 1360 gm — approximately 10 per cent more than normal for this age. Coronal sections showed a slight pink tinge in some places in the white matter, and the nuclei of the brain stem and medulla were pinker than normal. The petrous and mastoid bones and accessory nasal sinuses were not remarkable. The spinal cord did not appear grossly abnormal except for a slight pinkness of the cut surfaces of the anterior horns in the cervical and lumbar enlargements. A blood culture showed no growth in 9 days. Other tissues and organs showed no lesions.

Microscopical examination of the thrombi from the dural sinuses revealed a few organizing fibroblasts. The dura was not inflamed, and the thrombi were not adherent. The pulmonary alveoli contained gastric contents, and there were small hemorrhagic areas throughout the lungs. The basal ganglia and midbrain nuclei showed dilated blood vessels. The excised wound showed new fibrous tissue deep in the wound and close to a nerve bundle, but there was no foreign material or foreign-body giant cells about the wound. Other tissues showed no histologic lesions.

According to Pratt's¹ method of rating, this case may be considered one of moderately severe tetanus infection. In retrospect it is thought that closer attention should have been paid to hydration and dietary status, in view of the extremely warm weather and the patient's perspiration. The dural sinus thrombosis may well have been the result of dehydration, as shown by Bailey and Hass.² It might have been well to have given half the initial dose of 40,000 units of antitoxin intravenously to fix rapidly any circulating toxin, but the total dose was adequate according to Pratt,¹ although inadequate according to Vinnard.³ Penicillin might have been given earlier and in greater doses with good effect.^{4, 5}

This case demonstrates the advisability of active immunization against tetanus infection early in childhood. It also shows the necessity for early and complete débridement of wounds likely to harbor tetanus bacilli and the wisdom of administering antitoxin in adequate amounts soon after injury in nonimmunized persons.

The unique feature of this case, the aseptic dural sinus thrombosis, appears to have been the direct cause of death. According to Bailey and Hass,² few patients survive this condition, and autopsy of survivors shows severe brain damage. In 52 per cent of the 80 cases reported by these authors, the dural sinus thrombi were septic. All the patients with nonseptic dural sinus thrombi were less than thirty months old, and the average age was nine months. As a rule a period of extreme hyperthermia precedes death. The patient in the case reported herein was six years old and had a rectal temperature of 106.6°F three days before death.

Neurologic signs in these cases are diverse and undependable. The spinal fluid may or may not be under increased pressure, it is usually xanthochromic and contains 10 to 1000 red cells per cubic millimeter. Tests for increased globulin are generally positive, the sugar level is normal.

The terminal findings in this case may be correlated with the dural sinus thrombosis, which probably began to form on the seventh hospital day.

SUMMARY

A case of tetanus in which death was probably due to an aseptic dural sinus thrombosis is reported, and certain of the unusual findings are discussed.

MEDICAL PROGRESS

PULMONARY TUBERCULOSIS

J D WASSERSUG, M D *

QUINCY, MASSACHUSETTS

ALTHOUGH a voluminous literature covering the field of pulmonary tuberculosis has appeared during the last year, few outstanding advances have been made. Many papers, however, deserve mention because of their help in the diagnosis and treatment of the disease.

CONTROL AND CASE FINDING

In the last few years, since the advent of the miniature roentgenogram, case finding has achieved an unprecedented popularity. Fortified by public funds, the United States Public Health Service and other agencies are now well in the midst of programs to search for tuberculosis in every nook and cranny in this country. As a result, the number of known cases of tuberculosis has increased, but facilities for their care in sanatoriums have not expanded at a comparable rate. This lag in accommodations is noted and lamented in many recent publications.

Hilleboe¹ estimates that at the end of 1945 about 20,000,000 persons in the United States aged twenty years or older (1 in every 5 adults) had chest roentgenograms taken by the armed forces, health departments, industrial firms or voluntary agencies. But case finding is only one step in the control of tuberculosis, isolation and treatment are equally important. Patients with cases of active tuberculosis must be given medical care and must be isolated to prevent further spread of the disease. Hilleboe points out that there is a lack of vision in case finding if treatment is delayed by a shortage of sanatorium beds, adding "In every industrial community in which a tuberculosis control campaign is undertaken, plans must be made for the provision of a sufficient number of beds. Temporary facilities may, for a time, be utilized until the people, realizing the seriousness of the community's plight, will demand the construction and maintenance of the necessary hospitals."

Elsewhere, Hilleboe and Gillespie² phrase this same thought somewhat differently:

Unfortunately, after a physician has made a diagnosis of active pulmonary tuberculosis and has recommended sanatorium care, it may be found that sanatorium beds are not available. Therefore, it is necessary for physicians to care for these patients at home. This means that the physician must employ techniques used in the modern sanatorium including bed rest, nursing care, isolation, precautions, and general and personal hygiene.

If a physician keeps a patient close to the sanatorium routine at home while awaiting admission to a sanatorium, he is frequently surprised, at least in my experience, at the progress the patient exhibits in a short time.

The trend of the times in case finding is further illustrated by statistics from the State of New York, where Mikol and Plunkett³ report that from 1924 through 1939 in men, and from 1924 to 1941 in women, there was an almost steady decline in the annual number of cases of respiratory tuberculosis. Among the former a striking reversal of this trend began in 1940, reaching a peak in 1942, during which the number of cases was 38 per cent higher than in 1941. This increase was largely due to an increase in the minimal cases in the age group from twenty to thirty-four years. Mikol and Plunkett believe that this increase is due to the discovery of more cases by the various mass surveys rather than to any actual increase in the development of new cases. The greater incidence of pulmonary tuberculosis in young men and women is probably more apparent than real.

The extent to which case finding and hospitalization of discovered cases will eventually lower the tuberculosis death rate is not known. Nor are there reliable data regarding the number of early cases that will reactivate in spite of prompt hospitalization. Nevertheless, the tuberculosis mortality rate continues to show a gratifying decline. In the United States in 1944 it was at its lowest figure 41.3 per 100,000 population, as compared with 42.6 in 1943 and 43.1 in 1942. In Massachusetts, the death rate in 1944 was 40.8, as compared with 42.7 in 1943. According to preliminary estimates for 1945, the number of deaths from tuberculosis has continued to decline, but no exact figures are available. It must be pointed out, however, that statistics collected during the war years are not wholly reliable because of both the large shift of population groups and the considerable number of the population that has been overseas.⁴

Tuberculosis in Persons over Fifty

Myers⁵ points out that tuberculosis mortality is higher among Americans after the age of fifty years than at any other time in life, and that this fact is apparently not generally recognized, as indicated by the belief that human beings rarely have tuberculosis in the later decades of life. Since the average

*Instructor in medicine Tufts College Medical School

age of the population is increasing, the number of cases of tuberculosis in the aged is showing a commensurate rise. Besides, the disease in the elderly may be even more prevalent than mortality statistics suggest, since a significant number of deaths are not accurately reported. Myers cites the case of a man who had had a cough and a positive sputum for thirty years and who had presumably infected two daughters. At the age of eighty-two this man spent the winter in another state, where he became acutely ill and died within twenty-four hours. The local physician had no opportunity to examine him adequately. On the death certificate the cause of death was stated as "coronary disease," and no mention was made of tuberculosis.

Although tuberculosis is frequently discovered in elderly persons, Myers cautions that the diagnosis should not be made without adequate evidence. An aged person with a chronic cough and expectoration does not necessarily have pulmonary tuberculosis. Symptoms, signs and x-ray appearance are not pathognomonic. The only absolute diagnostic finding is the presence of tubercle bacilli, confirmed by culture or animal inoculation.

Tuberculosis among Nurses

On the basis of considerable evidence obtained from reviewing the medical literature and from his own experience, Cameron⁶ believes that nurses are exposed to a real hazard while caring for tuberculous patients. He emphasizes that nothing is gained by minimizing the facilities for tuberculous infection that exist in a sanatorium. Reported statistics indicate that the incidence of tuberculosis among nurses varies from 1.6 to 6 per cent, with a probable average of about 3 per cent. Yet, surprisingly, practically all superintendents of sanatoriums agree that tuberculous disease among their staffs is rare. The reason for this apparent contradiction, Cameron points out, lies in the fact that there is no follow-up of those employees who have left the institutions. Another possible reason is that many nurses are covered by the blanket classification "housewife" in hospital statistics and reports. Actually there are many registered nurses, attendant nurses and various ward helpers whose occupation at the time of admission to the sanatorium is "housewife" and whose earlier employment and possible infection are ignored.

Statistics regarding tuberculosis among nurses are probably much too low. Cameron observes that the repeated infections to which nurses are exposed are an undoubted risk. The greatest danger, of course, lies in young girls whose reactions to the Mantoux test are originally negative, although there is theoretical danger even to those whose reactions are positive. Cameron carries this thesis still farther, pointing out that to control tuberculosis among nurses working in sanatoriums the administrators

should concern themselves with the mental and spiritual well-being, as well as the physical status, of the employees. He writes as follows:

An emancipated spirit fortifies a well-tended body, and strength of body and serenity of mind are the best defences against tuberculous invasion. The living and working conditions of tuberculosis nursing must be good. Mental freedom is just as important as physical well-being.

It is my belief that if more sanatorium administrators placed greater value on the wisdom of these words, there would be far less of a nursing shortage in many institutions.

Tuberculosis in Repatriated Prisoners

Brooke⁷ provides a partial answer to the question of the extent of tuberculous involvement in repatriated prisoners of war. Of course, his figures are not wholly adequate in that they do not include patients who died in prison camps because of the disease. Of 1507 prisoners repatriated from Japanese camps he found that 118 (7.8 per cent) had active or questionably active pleural or pulmonary disease. Of these, 24 were believed to be questionably minimal, and 33 minimally active. Repatriated prisoners had a lower incidence than had been anticipated.

Tuberculous Families and Household Associates

Many workers have speculated on the factors that control the incidence of clinical tuberculosis in a given household. It is a frequent clinical experience that not every person in a household develops active tuberculosis even when the extent of the exposure to an open case is roughly comparable in all the members of the household unit. To determine the reasons for this variability, Puffer and her associates⁸ investigated family contacts in Williamson County, Tennessee. Careful studies of the associates of 519 white and 111 colored index cases revealed that the prevalence among white associates increased from a low rate in persons under fifteen years of age to a high rate for those thirty-five years and over. The incidence among colored associates did not show this distribution; relatively high rates were found in all age groups. In white associates thirty-five years of age or older 12.9 per cent of the blood relations had manifest tuberculosis, whereas only 7.4 per cent of those not related had the disease. In the age group fifteen to thirty-four years the attack rate for white household associates related by blood was 0.8 per cent, and for those not related it was 0.3 per cent. Obviously, blood relatives show a greater attack rate and a greater prevalence rate than those not related.

These data are supplemented by the report of Telford and Garten-White,⁹ of the Los Angeles County Health Department. Whereas they had been inclined to discount the lay conception that there is a familial susceptibility or resistance to the disease,

they are forced to conclude that there may be some factual or at least statistical basis for this relief. Their figures showed that a comparatively small proportion of the families exposed presented nearly all the new cases, and they believe that the attributes that make these families more than ordinarily susceptible deserve earnest study. If the characteristics of these groups can be recognized, public-health efforts can be devoted more intensively to such families than to the community at large.

It is pointed out that a crowded living condition, although a major contribution to a greater familial incidence of tuberculosis, is not the only factor involved. A survey of patients in 1940, for example, revealed that about 50 per cent of 1637 contacts developed active reinfection tuberculosis six months or more after the discovery of the first known case in each of the families. In 1944, in spite of apparently improved social and economic conditions, the attack rate was found to be insignificantly lower—4.8 per cent. Other surveys conducted at the same time in congested areas yielded an attack rate of only 0.5 per cent. The great hazard in families with a high attack rate is apparently due not only to the direct spread of the infection but also to other factors and conditions favoring the spread. Telford and Garten-White therefore believe that some inherent fault in either physical or mental make-up makes the members of such families more susceptible than the average person, or that contributory domestic habits have not been overcome by the usual public-health education and supervision. They write as follows: "Isolation of active cases of tuberculosis, either outside the home or in the home with intensive supervision, should be stressed in proportion to the number of cases in the family or to cases known in the recent family history."

On the basis of these detailed investigations one can reasonably conclude that it takes more than mere contact with the tubercle bacillus to develop clinical disease. The factor of familial susceptibility must be considered in the management and prognosis in any given case. Further elucidation of the factors of familial susceptibility is certainly indicated.

ANATOMICAL CONSIDERATIONS

Since bronchoscopy and surgery are playing such an important role in the diagnosis and treatment of pulmonary disorders, a wider understanding of the segmental anatomy of the tracheobronchial tree is essential. Localization of a pulmonary lesion in relation to its appropriate bronchopulmonary segment often helps clarify the nature of a suspicious roentgenologic shadow, and may provide a clue to its proper management. No longer can it be considered adequate to describe a "spot" as being at "the level of the third anterior interspace." In the following three studies¹⁰⁻¹² one can obtain the essentials for a more complete understanding of the tracheobronchial tree and its pulmonary segments

as viewed by the anatomist, the bronchoscopist and the roentgenologist.

The anatomist's point of view is presented by Boyd¹⁰ in a series of excellent dissections and exquisite colored plates. Briefly, some of the significant facts are as follows:

Right bronchial tree. The upper or *superior-lobe bronchus*, which arises almost at the bifurcation of the trachea, is very short, branching almost immediately into three stems—the apical, anterior and posterior segmental branches. The apical segmental branch divides into anterior and posterior rami. The anterior one divides into a lateral ramus going to the axilla and an anterior ramus descending to the inferior portion of the upper lobe. The posterior segmental branch divides into a posterior ramus, with its posteriorly placed orifice and its predilection to abscess, and a lateral ramus. The *middle-lobe bronchus* divides into a medial and a lateral segmental bronchus, which show considerable anatomic variation, and there is some shifting from one segment to another. For this reason resection of either the medial or lateral segment is technically difficult, and if operation is indicated both segments are usually resected together. The *lower-lobe bronchus* divides first into a superior segmental bronchus, which has a posterior horizontal distribution and, surgically, can be readily identified and removed separately. Between the superior bronchus and the remaining segmental bronchi of the right lower lobe there is an interval of 1.5 cm., which is the common stem of the four segmental bronchi that reach to the base or the diaphragmatic surface of the lung.

Left bronchial tree. The upper or *superior-lobe bronchus*, which originates farther down on the left side than on the right, arises from the anterolateral instead of the posterolateral surface of the main bronchus. It divides into a superior and a lower (or lingular) division. The upper division gives off an apical posterior segment and an anterior (or pectoral) segment. The lower or lingular division has superior and inferior segments, the lingula being analogous to the middle lobe on the right. The inferior or *lower-lobe bronchus* gives off several segmental branches that are designated as superior, anteromedial basal, lateral basal, and posterior basal. As on the right, the superior segment has its orifice posteriorly, close to the point of origin of the bronchus itself. The basal segments on the left differ from those on the right in that they are three in number instead of four and usually branch by trifurcation rather than by bifurcation.

Hagens¹¹ dissected the lungs of 20 cadavers to clarify the appearance of the bronchial tree from the standpoint of the bronchoscopist. He was thus able to map out the various orifices that are such important landmarks, to determine their diameters and to make many measurements to establish their usual relations. This paper should be read in conjunction with that of Boyd,¹⁰ since the data and descriptions tend to supplement each other.

Clarification of the anatomic arrangement of the tracheobronchial tree makes more readily understandable the valuable series of articles by Robbins and his associates¹²⁻¹⁴ on the roentgenologic appearance of the segmental collapse of the lung. These investigators recommend that when pulmonary disease is suspected the patient be studied fluoroscopically and that in addition he have a routine posteroanterior film, a lateral film and an anteroposterior Bucky or Swedish-grid roentgenogram. With these few studies approximately 80 per cent of patients with pulmonary disease need no further roentgenologic investigation to establish the diagnosis. The usual diagnostic criteria of segmental

collapse of the lung, Robbins et al point out, are an abnormal shadow of increased density, elevation of the diaphragm, displacement or shift of the mediastinum and narrowing of the rib spaces. After a detailed analysis of 1200 cases of tumor, bronchiectasis, foreign body and tuberculosis, they were able to add three more criteria to this original list: the appearance and position of the hilar shadows, the arrangement of the vascular shadows and the demonstration of the actual size of a lobe as determined by the appearance and position of the septums or fissures of the lung. Displacement of a hilus upward, for example, indicates possible collapse of an upper lobe.

Although collapse of an entire lung or a major portion thereof is usually readily recognizable from established criteria, segmental collapse may be more difficult to identify. Collapse of a lower lobe occurs rather frequently but is often overlooked or misinterpreted because the shadow of increased density is small and so located that it is hidden by overlying structures, such as the spine, diaphragm and mediastinum. Usually the first sign of collapse of a lower lobe is a posterior displacement of the interlobar septum. Lung markings of the collapsed lobe later become crowded together. If the collapse is confined to the dorsal division of the lower lobe it may be identified as a triangular area of density and by the sharp angulation of the posterior portion of the major interlobar septum. Since bronchiectasis usually spares the dorsal division, whereas tuberculosis and lung abscess are often found in that area, accurate localization of the collapse is frequently an aid in differential diagnosis.

Collapse of the right middle lobe of the lung also occurs frequently but is often confused with interlobar effusion. Complete obstruction of the bronchus to the right middle lobe causes the lobe to decrease in size and assume a pyramidal shape, with the base against the right border of the heart and the apex extending toward the lateral chest wall. The result is a loss of definition of the right border of the heart. In this event the lateral view is the most important single factor in the examination, and its appearance may be deceptively like that of a pleural effusion. A lordotic view may help further in the differentiation of these two conditions.

Collapse of a single lobe of a lung is most frequently misinterpreted in one of the upper lobes, where it is confused with a localized area of consolidation, a mediastinal tumor or an aortic aneurysm. In some cases it may be completely overlooked. One of the first signs of collapse of an upper lobe is displacement of the major septum anteriorly and superiorly as determined in the lateral film. Careful attention to detail on all the x-ray films is essential to accurate diagnosis of collapse and to differentiation from other pathologic conditions.

An understanding of the bronchial pattern also helps in an evaluation of the status of a bronchus

that drains a tuberculous cavity. According to Camiel,¹⁴ the roentgenologic appearance of the lung in the area between a tuberculous cavity (or the site of a previous cavity) and the hilus is of special importance. This portion of the lung contains the regional bronchi and the peribronchial vascular and lymphatic channels that drain the area of the parenchymal lesion toward the lung root. These draining bronchi, which are frequently involved in the tuberculous process, can often be visualized roentgenologically, and their appearance depends on the severity and duration of the underlying process or disease. Bronchial thickening due to edema or thickening resulting from extension of the disease into the bronchus with subsequent fibrosis increases the visibility of the bronchial shadow and thus makes possible a diagnosis of endobronchial tuberculosis.

BRONCHOSPIROMETRY

With the greater interest in the detailed anatomy of the bronchial tree during the last few years there has been a corresponding interest in greater refinements of technic for determining the functional capacity of the lungs. In many cases it is no longer adequate to make one determination of a patient's vital capacity in the belief that it provides a reliable gauge of his pulmonary function. The vital capacity can be considered rather as a rough guide that fails to disclose any information concerning the function of each lung and therefore may be misleading.

Bronchspirometry, on the other hand, provides the additional data that are often lacking. With this procedure it is possible to make many different determinations on each lung (such as tidal air, respiratory rate and vital capacity) and to decide what functional share each lung is contributing to the total. Some of the significant facts that can be learned from bronchspirometric studies have been recently reviewed by Pinner, Lein^{er} and Zavod,¹⁵ who found that bronchspirometry often revealed decreased function in one lung when regular spirometric studies were normal or nearly normal. For example, they cite the case of a twenty-nine-year-old man with right pneumothorax, whose vital capacity on spirometry was 2650 cc. Maximum breathing capacity divided by minute volume was 11.3, a finding consistent with a normal respiratory reserve. Yet on bronchspirometry the oxygen intake of the right lung was discovered to be only about a third of the total oxygen intake in spite of a normal respiratory reserve; the right lung contributed only about 30 per cent of the total oxygen intake instead of its normal contribution of 54 per cent.

One of the most valuable findings resulting from these bronchspirometric investigations is the demonstration that a marked discrepancy may exist between the clinical findings, the x-ray appearance and the actual function of the lung. Cases are cited

to show that a slight amount of fibrosis (as determined by x-ray study) may be accompanied by a considerable amount of functional damage. Conversely, in a lung that appears on x-ray examination to be heavily infiltrated or even riddled by cavities, the impairment in function is hardly appreciable. Curiously enough, when special studies were made on patients whose lung function was extremely poor, it was found that practically all these patients had either obliterative pleuritis or phrenic paralysis. Pinner et al. emphasize the fact that pleural involvement that cannot always be diagnosed by roentgenologic examination may lead to severer functional damage than a more obvious parenchymal lesion.

Collapse therapy (pneumothorax) causes a reduction in the oxygen intake of the collapsed lung. Compensation for this decrease is accomplished by both a commensurate increase in the contralateral lung and a cardiovascular factor. The respiratory burden on the contralateral lung is considerably less than one might anticipate. It therefore follows that if a patient with unilateral pneumothorax is dyspneic at rest, the cause is not likely to be found in the extent of his collapse but rather in a possible functional impairment of the contralateral lung. That therapeutic pneumothorax (or the disease itself) may leave the lung with permanent functional disability is demonstrated by the fact that re-expanded lungs show some degree of respiratory impairment. Twenty-six cases of thoracoplasty studied showed surprisingly less diminution in pulmonary function than those treated by pneumothorax. But, as Pinner and his colleagues¹⁵ point out, more cases will have to be explored by this method before it can be certain that the differences detected are not merely the results of random sampling. An interesting side light brought out by bronchspirometric investigation is that immobilization by sandbags or by strapping with adhesive does not achieve a reduction in the ventilation or the respiratory work of the underlying lung.

Tests of pulmonary function, in a way, are analogous to those of renal function. In diffuse bilateral disease, the total function (as determined by routine spirometry) may provide all the data that the clinician needs. On the other hand, in unilateral disease or in predominantly unilateral disease or when surgery is contemplated, data regarding the function of each lung separately may provide invaluable information.

BED REST

The recent discussions covering strict bed rest as a method of treatment have stimulated renewed interest in this type of therapy for tuberculosis. Obviously, strict bed rest is not without its limitations and contraindications in tuberculosis as in many other ailments. Peck¹⁶ described the progress of a group of patients at the Detroit Municipal Tubercu-

culosis Sanatorium who were placed on a regime of bed rest with instructions never to sit up, never to raise the head from the pillow and to lie as inertly as possible. Difficulties soon began to appear. Cough frequently increased, with roentgenologic evidence indicating poor drainage of secretions, and a few patients showed serious extension of the disease. Many complained of increased nervousness and fatigue. Peck concluded that strict bed rest may at times be harmful and may actually defeat the purpose for which it is given.

It was recognized soon after this experiment that rest in the supine position violated a well established surgical tenet — that drainage from abscess cavities must be free and adequate. Since most tuberculous cavities are posteriorly placed, such a position interferes with drainage, makes the cavity dependent, encourages toxicity and enhances spread. Because of these considerations, the regime at the Detroit Municipal Sanatorium was modified to allow the patient reasonable motion in bed, adequate drainage of cavities, relief from bronchial spasm and liquefaction of sputum by means of steam inhalations. The problems of muscular relaxation and mental repose — a much neglected aspect of treatment in the routine management of sanatorium cases — were also given consideration.

This new regime of treatment was then applied to 69 patients, most of whom had extensive bilateral disease and cavitation. Of these, 19 had cavity closure with conversion of sputum, 14 responded favorably enough to permit thoracoplasty, 26 were studied for an insufficient length of time, and 10 died. In a control group of cases (the difficulties in finding true controls are admitted), selected because of similar age and comparable lesions by roentgenogram, only 2 patients had cavity closure and sputum conversion, 7 progressed to thoracoplasty, 12 were discharged improved, and 48 died. In Peck's opinion carefully supervised bed rest is effective therapy, giving results entirely commensurate with the time and energy involved.

Elsewhere, Peck and Willis¹⁷ direct criticism to so-called "postural rest," in which patients with unilateral cavitation are encouraged to lie on the cavity side with the idea that the uninvolved lung will be protected from positive sputum. They believe, with good reason, that such an argument is fallacious and that postural rest cannot maintain unilateral sepsis. They cite the case of a thirteen-year-old girl who had been kept on one side for three months, with consequent bathing and saturation of the dependent lung in its own secretions. Examination showed that this girl had extensive bronchiectasis of the upper lobe of the dependent lung, which may well have developed as a direct result of improper bed rest. No physician would give the same dose of insulin to all his diabetic patients, and yet the same dose and same type of bed rest is prescribed for all tuberculous patients in some sanatoriums.

This condemnation of strict bed rest for all patients is carried still farther by Brav,¹⁸ of the New York State Hospital for Incipient Tuberculosis, who points out that few published reports substantiate the alleged value of strict bed rest for tuberculous patients who are in a good nutritive condition and entirely or practically free from symptoms. Contrary to some expressed opinions, early tuberculous lesions, especially those in the upper part of the lung, have a marked tendency to heal and are usually not progressive. This point is readily demonstrated in Brav's studies of 67 cases, whose lesions were less than a year old as determined by serial roentgenograms. In no case did the patient receive strict bed rest, all were ambulant from the time the disease was discovered, throughout their sanatorium stay and subsequently, for a period averaging thirty months. The results were favorable in 57 (85 per cent of these cases). Although the number of cases was too small for definite conclusions, this experience is comparable to the best statistics obtained with strict bed rest. Bed rest, like any other form of therapy, should be individualized both in the early and in advanced cases.

An ingenious but still unproved theory advanced by Dock¹⁹ to account for the apical localization of pulmonary tuberculosis has some bearing on bed rest. Dock points out that in man the mean pulmonary arterial pressure is equivalent to 15 to 18 mm of mercury, which, in turn, is equivalent to a column of blood 12 to 23 cm in height. Since the apex of the lung is 15 to 30 cm cephalad to the right ventricle, the pulmonary arterial pressure in the upper 5 cm of the lung, even in systole, is at most equivalent to 10 mm of mercury. Because a pressure equivalent to about 15 mm. of mercury is required to overcome the difference in colloidal osmotic pressure between the plasma and the pulmonary tissue fluid, it is likely that no lymph is produced in most adults while they are in the erect posture. As a result, it is claimed, few lymph-borne and cellular antibodies reach the apical portions of the lung while a person is sitting or standing.

But Dock affirms that this fact does not mean that a person with tuberculosis must lie flat on his back all the time, it simply means that if he is taking bed-rest treatment he should be recumbent and not sitting up. At least part of the day should be devoted to recumbency to overcome the hydrostatic pressure within the pulmonary circuit. Dock's conclusion is as follows:

It is quite possible that if the patient were allowed up, when he felt strong enough, for ten to thirty minutes four or five times a day, his moral and physical strength would be better preserved or more quickly restored. Even if this were permitted in the mornings, when the afternoon temperatures were elevated, it might do more good than harm.

Such a program might enable a patient to accept recumbency as a therapeutic measure with a greater

degree of physical and mental ease and might thus make the entire treatment more effective.

PLEURISY WITH EFFUSION

It is becoming increasingly evident that pleurisy with effusion, especially in young adults, most frequently has a tuberculous etiology. Farber's²⁰ recent follow-up studies clearly demonstrated that a significant number of patients with pleural effusion develop pulmonary tuberculosis. Of 111 patients followed for three years or longer, 38 (34 per cent) developed parenchymal disease, and 27 died. This indicates that the prognosis in cases of pleurisy with effusion should be guarded.

More recent investigations are consistent with this point of view. For example, Bird's²¹ evaluation of the clinical course of 7 cases of alternating pleurisy with effusion in patients between the ages of twenty-one and thirty-six, with an average age of thirty-two, demonstrated a tuberculous background in all but 1. In several cases, tubercle bacilli were found on culture or guinea-pig inoculation when direct smears were reported as being negative. It must be stressed that the more delicate the test, the greater the likelihood of recovering the tubercle bacillus. Close²² also found that as the bacteriologic technic improved, the number of proved positive cases increased from an average of 40 per cent to one of 70 per cent. In his most recent series of cases, among 159 young adults hospitalized for pleural effusion he recovered tubercle bacilli by culture on the Lowenstein-Jensen medium in 90 per cent of the cases in which the diagnosis of tuberculosis was eventually made on clinical grounds. He states: "No opportunity for culturing should be neglected. Even 1-2 cc of what looks like blood from an unsuccessful attempt at aspiration should be put on culture medium. From three such lung punctures tubercle bacilli have been obtained."

Similarly, Feldman and Lewis²³ are of the opinion that bacteriologically sterile effusions carry the same import as those that are positive, active caseous tuberculosis being directly responsible for the onset of the effusion even when the fluid remains sterile. At the Rhoads General Hospital they thoroughly investigated 59 patients with pleural effusion, especially for the presence of tuberculosis. The fluid was on the right side in 39 cases, on the left in 18 and bilateral in 2. The onset of the disease was described as "insidious" in 34 cases, "acute following a prodrome" in 18, and "acute, fulminating" in 9. In 2 cases with insidious onset, the patient developed a fresh pleural effusion on the opposite side after the original one had subsided, both cases had suggestive parenchymal infiltration and hilar enlargement. Feldman and Lewis conclude that pleural effusion occurring in young persons in whom no other readily demonstrable cause exists can be considered tuberculous until clearly proved otherwise.

Since tuberculosis figures so significantly in the etiology of pleurisy with effusion it is essential that these patients be followed, like any tuberculous person, by frequent check-up and x-ray examinations. Feldman and Lewis recommend such a follow-up to extend for five years after the onset of the effusion, with special emphasis on the first year. For therapy, they advise complete evacuation of the chest (in stages, if necessary) and the introduction of 200 to 300 cc of air into the pleural cavity to obtain better x-ray visualization of the lung parenchyma. It seems logical that if tuberculosis is suspected, the contacts of all patients with pleurisy and effusion should be investigated to determine the possible source of the infection.

CHEMOTHERAPY AND ANTIBIOTICS

Streptomycin

Each year some new therapeutic weapon seems to offer the victims of tuberculosis a quick and dramatic rescue from their long and costly illness. This year the "hope on the horizon" is streptomycin. Although its precise indications and limitations have not been worked out in human tuberculosis, there can be no question about its effectiveness in animals. Injected into guinea pigs, streptomycin was found to exert a striking inhibitory action on the activities of *Mycobacterium tuberculosis* in vivo but did not succeed in eliminating or killing all the bacilli in the animals.²⁴ In mice, whose resistance to tuberculosis is greater than that of guinea pigs, a comparable effect was noted, and the suppressive action was characterized as marked even though the tuberculous infection was not completely suppressed.²⁵ After a more extensive and better controlled series of experiments, Hinshaw and Feldman²⁶ reported that streptomycin appeared to be more effective than any of the sulfonamide drugs and much less toxic for guinea pigs.

Under the direction of Hinshaw and Feldman²⁶ streptomycin therapy for human tuberculosis was begun in December, 1944. At first, small ineffective doses were used, with inconclusive results. With further knowledge of the pharmacologic properties of the drug, it was soon established that the minimal daily dosage should be 800,000 "S" units (1000 "S" units equal 1 mg of streptomycin), and usually the patients received from 1,000,000 to 2,000,000 units by intramuscular injection at three-hour intervals. No serious toxic effects were noted, but in 4 cases sensitization to the drug was apparent, so that violent febrile reactions developed when the drug was administered after an interval of a few weeks. In some cases transient deafness and disturbance of vestibular function were observed, but it is not known whether this was due to the streptomycin or to some impurity. At any rate, of the 16 patients treated for one to three months, no rapid curative action was seen. Lesions that were soft and of known recent

origin tended to improve promptly, but in some cases there was reactivation when the drug was discontinued. All that could be said for streptomycin was that it had a limited suppressive effect.

Subsequently, in a more detailed report, Hinshaw and Feldman²⁷ cited their experience with 54 patients with tuberculosis who had received streptomycin treatment for periods of more than four weeks. In each case the disease had shown a tendency toward unfavorable progression prior to the institution of therapy. In 21 cases the patients had pulmonary tuberculosis, which in 16 was far advanced with the addition of infiltrations of recent origin. Of the 21 pulmonary cases studied, objective evidence of improvement was observed in 16. An antibacterial action was not noted, but a suppressive effect was found so long as administration of the drug was continued. Streptomycin was also used in cases in which there were tuberculous sinuses, but in 3 of 5 cases the sinuses recurred after the drug was discontinued. In tuberculous empyema and in urogenital tuberculosis the results must still be regarded as inconclusive.

Supplementing this report by Hinshaw and Feldman, Cooke and his colleagues,²⁸ at the Yale University School of Medicine, recorded the recovery of a child with tuberculous meningitis. The infant was admitted to the New Haven Hospital on May 12, 1945, with convulsions, and the diagnosis of tuberculous meningitis was incontrovertibly established. Streptomycin was begun seven days later and continued for thirty days. Therapy was discontinued because of lack of the drug, but was resumed on July 9 for an additional twenty-nine days. At the time the report was written (December 31, 1945) the child was still alive and apparently improving, although there were some residual neurologic impairment, cervical adenopathy and abnormal pulmonary findings. Acid-fast bacilli had not reappeared in the spinal fluid, however.

Other Antibiotics

The *Bacillus subtilis* produces a substance called "subtilin" that has a bacteriostatic action in vitro against the tubercle bacillus in high dilution (1:100,000) and appears to be germicidal in greater concentration (1:50,000).²⁹

Mattick and Hirsch³⁰ isolated a streptococcus that destroys tubercle bacilli in vitro. On exploring the widely held notion that the acid in sour milk had a destructive action on tubercle bacilli, they found that it was not the acid per se or the lactic streptococcus that was responsible for the tuberculocidal action of sour milk, but another streptococcus — "the inhibitory streptococcus." This organism, they claim, produces sufficient antibiotic substance to kill or render avirulent up to 2000 tubercle bacilli per cubic centimeter of milk. These tests, which are preliminary, await confirmation.

Chemicals

Clinical interest in the sulfonamides is waning — perhaps rightly so. Their value in clinical tuberculosis is less than the earlier results seemed to indicate. For example, at the Firland Sanatorium in Seattle, diasone was given to a group of 10 patients for one hundred and nineteen days without any appreciable alteration in the course of the disease as compared with a group of controls.³¹ Neither the sputum nor the x-ray findings showed any benefit. Similarly, at the Chicago Municipal Tuberculosis Sanatorium, Tice and his co-workers³² failed to note any improvement when the therapy was adequately controlled. In their tests, 29 patients with far-advanced tuberculosis were given diasone, but only 16 completed the course of therapy for one reason or another. After six months the results in the diasone-treated patients and in the controls ran parallel. Five of the former and 4 of the latter improved, whereas there were 14 unimproved treated patients and 11 unimproved controls, and 10 dead treated patients and 15 dead controls.

Both the chorioallantoic membrane of the chick embryo and the anterior chamber of the guinea pig's eye have been found to serve efficiently in the evaluation of new drugs for their possible bacteriostatic action. Thus, Steenken and his colleagues³³ showed that ocular tuberculosis in the guinea pig could be fairly well controlled and retarded in its progress by both the oral administration and the local instillation of promin. The method of eye infection offered a relatively rapid and easily observable method of testing new chemotherapeutic agents for the treatment of tuberculosis.

Twelve different alicyclic acids — chemically related to chaulmoogra oil — were tested by Emmart³⁴ in vitro and four were also studied in vivo (chick embryo) for tuberculostatic action. Four cyclopentyl and cyclohexyl compounds were found to be highly tuberculostatic in relatively low dosage. Emmart believes that further animal studies with these chemicals will prove profitable.

MISCELLANEOUS TOPICS

Amyloid Disease

Chronic suppuration, tuberculous or otherwise, usually leads to amyloid disease, which is almost universally regarded as having a poor prognosis, although the interval between the onset of symptoms and death varies considerably from patient to patient. Jacobi and Grayzel³⁵ recently directed attention to the therapeutic benefits of liver for such patients. In their series of 69 cases all the nontreated patients died, whereas 9 of the 16 treated patients were definitely cured and 3 others showed clinical improvement or prolongation of life. They recommend that in addition to intensive treatment of the primary infection, the patient be given 2 to 8 gm of desiccated powdered whole liver three times daily. Since not all liver preparations are comparable in

their potency against amyloid disease and since the treatment is long and costly, fresh liver may be prepared according to directions given by the authors.

The relation between amyloid disease and the necessity for surgical treatment often creates perplexing problems. To determine whether patients with amyloid disease are benefited or harmed by surgery, Auerbach and Stemmermann³⁶ analyzed the records of 486 cases of amyloid disease in which the diagnosis was proved by autopsy. Forty-three patients had fifty-two major surgical operations after the detection of amyloid disease, and 43 had seventy-seven operations prior to the development of this complication. On the basis of these cases, which were comparable in many respects, Auerbach and Stemmermann concluded that the decision to operate is not to be determined by the existence of the amyloid disease itself but by the possibility of controlling the underlying infection. Control of the original infection provides the patient with his best chance for recovery. The presence of amyloidosis should be an added indication rather than a deterrent, according to the authors, who also believe that with evidence of renal or other visceral impairment, surgery becomes obligatory, for although such patients are poor risks, eradication of sinuses and arrest of infection offer the only hope of escaping death.

Tuberculous Laryngitis

Tuberculosis of the larynx is a serious complication of a pulmonary infection and one that is notoriously difficult to treat. According to Humphries³⁷ treatment of tuberculous laryngitis may be regarded as being both medical and surgical. For medical therapy he recommends comforting spray and voice rest. Under surgical treatment he lists galvanocauterization, laryngoscopy, biopsy, nerve block, tracheotomy, arytenoidectomy, bronchoscopy, and collapse therapy. Bronchoscopy is practically never indicated for laryngeal tuberculosis, although it plays an important role in the management of lesions deeper within the bronchial tree. Collapse therapy, by ridding the sputum of tubercle bacilli, has an indirect beneficial action on laryngeal disease. Most satisfactory of all, according to Humphries, is electrocauterization, which gave marked relief in over 90 per cent of his cases.

Myerson³⁸ has advanced the hypothesis that it is not the ulceration of the larynx that is responsible for the patient's pain but the secondary infection of the involved tissues by pyogenic organisms. In support of this point of view he calls attention to the fact that spraying the diseased tissues with sulfanilamide powder brings immediate relief from pain. In his treatments a powder atomizer is used to spray between 0.3 and 0.6 gm of sulfanilamide into the larynx at each application. He has treated 60 patients in this way, with encouraging results. In 14 cases a hopeless condition became favorable following institution of therapy.

Gastric Juice and Tubercle Bacilli

Bacteriologic investigation of gastric juice by culture or by guinea-pig inoculation is often performed in the laboratory examination for tubercle bacilli. Yet there is some evidence that many false-negative reactions may have been obtained because of failure to inject the animals with fresh gastric juice.³⁹ If delay between the time the gastric juice is obtained and its inoculation into an animal is unavoidable, it is best that the specimen be neutralized before being allowed to stand. Three times more positive reactions can be obtained when the specimens are neutralized immediately than after forty-eight hours and nearly twice as many as after a twenty-four hour interval.⁴⁰

Vaccination

Although vaccination against tuberculosis with BCG (*Bacillus Calmette-Guérin*) has never been unanimously accepted, there is increasing evidence that the procedure is of value. This is particularly true in areas where tuberculosis is associated with a high mortality. An impartial evaluation of vaccination with BCG has been summed up in a concise and lucid fashion editorially.⁴¹ In support of the thesis that vaccination provides limited protection to heavily infected groups, the six-year results of Aronson and Palmer⁴² with groups of North American Indians may be cited. This report is based on the study of 1550 vaccinated Indians and 1457 controls who were resident in four widely scattered reservations. The initial testings and vaccinations were concluded in February, 1938, and the cases were followed annually until 1944. These studies showed that there were 60 deaths (from all causes) in the controls, but only 34 in the group vaccinated with BCG. Whereas 4 deaths from tuberculosis were recorded in the vaccinated group, there were 26 in the nonvaccinated. Forty cases of roentgenologically evident disease developed in the group vaccinated with BCG, and 185 cases were detected in the controls. Thus it appears that considerable benefit was obtained by this form of vaccination.

Attention was called in an earlier review⁴³ to the possibility of using the vole bacillus as an immunizing agent against tuberculosis. Present work with guinea pigs indicates that immunization with the vole bacillus takes place but that the degree of protection obtained is apparently no greater than that resulting from vaccination with BCG.⁴⁴

Expectorants

The continuing researches of Boyd and his colleagues⁴⁵⁻⁴⁷ are uncovering many new facts regarding the expectorant drugs. For example, they note that paregoric (camphorated tincture of opium) has been used for many years as a sedative in cough mixtures, with little investigation of its mode of action. But, by measuring the output of respiratory-tract fluid in different animals, they concluded that pare-

goric has considerable expectorant action, and that this action is greater than that of any of the individual components of paregoric or that obtained by a summation of the individual effects. Best results were obtained with preparations that had aged a year or longer. If the afferent vagal nerves from the stomach were severed, paregoric did not augment the respiratory-tract fluid—an indication that it acts reflexly through the stomach.

A variety of volatile oils have also been tested for their ability to stimulate respiratory-tract fluid. Of four terbinthinate oils tested, oil of turpentine proved most effective. Among the other volatile oils, oil of anise was most potent. The authors believe that if these data apply to man they indicate that oil of anise is not being used to its optimal extent as an expectorant drug. The expectorant volatile oils do not act reflexly from the stomach but rather on the secretory cells of the respiratory tract. The inclusion of several different expectorants in one cough mixture does not seem to enhance its expectorant action, as measured by respiratory-tract fluid.

Depth Growth of Bacilli

The growth of bacilli submerged in a liquid culture medium more nearly approximates that of the bacilli in living animal tissues than growth on the surface of a medium exposed directly to the atmosphere.⁴⁸ The technics for obtaining depth growth are described by Drea^{48, 49} who also points out that this type may be used to test the effect of various substances on the growth and nutrition of the tubercle bacillus. By submerged growth technics, Dubos⁵⁰ demonstrated that certain complex lipids had a remarkably stimulating effect on the multiplication of mycobacteria. Addition to Long's synthetic medium of small amounts of phosphatide and of long-chain fatty-acid esters enabled the organisms to grow far more quickly. Thus, with submerged growth technics, testing for tubercle bacilli is becoming both more sensitive and more rapid.

Calcifications, Coccidioidomycosis and Histoplasmosis

The long held dogma that all calcifications within the lung are due to tuberculosis is rapidly being shattered with the discovery of the role played by other micro-organisms. Further evidence of the ability of coccidioidomycosis to produce calcifications is brought out by the studies of Butt and Hoffman,⁵¹ who did coccidioidin tests on 1165 patients at the Santa Fe Coast Lines Hospital in Los Angeles and found that 302, or 26.0 per cent, were positive reactors. The greatest incidence of infection (62.8 per cent) was found in the group of patients coming from the San Joaquin valley. The calcifications of tuberculosis and those of coccidioidomycosis are practically identical, but in some cases the presence of apical scarring (in tuberculosis) helps differentiate the two conditions.

There is some evidence that infection with *Histoplasma capsulatum* may also be responsible for pulmonary calcifications. Palmer,⁶¹ who explored the geographic distribution of histoplasmin sensitivity in the United States by skintesting of 10,580 nurses in eleven different cities, discovered that sensitivity varies widely in different geographic areas, from a low of 5 per cent in and around Minneapolis to a high of 60 per cent in Kansas City, Missouri. In the New England states, 10 per cent of the nurses reacted to the histoplasmin.

To determine the cause of pulmonary calcifications in children in one county in Tennessee, Christie and Peterson⁶² tested 344 with tuberculin, histoplasmin and haplosporangin, and also had chest roentgenograms taken. Calcifications were found in 53.2 per cent, whereas only 21.5 per cent reacted to tuberculin. They regard this as further evidence that in many sections of the United States the prevalence of pulmonary calcifications is far in excess of that which can be explained by tuberculosis as revealed by tuberculin cutaneous testing. It is interesting to note that no child reacted to the haplosporangin, the specificity of the skin reactions thus being demonstrated. Reactions to histoplasmin were observed in 73.2 per cent. Of the group of 78 children who did not react to either tuberculin or histoplasmin, 14 (17.9 per cent) had pulmonary calcifications. Christie and Peterson conclude that present concepts of the primary complex or first-infection tuberculosis in its relation to pulmonary calcification need re-evaluation. The implications of these findings, which challenge a dogma that has existed for many years are nothing short of revolutionary.

CASE 32331

PRESENTATION OF CASE

A thirty-nine-year-old mechanic entered the hospital because of a chronic cough.

Coughing episodes began twenty years before entry; they occurred about twice a year, lasting two or three weeks and producing about half a cup of greenish sputum daily. Fourteen years before entry the patient had an attack of lobar pneumonia on the left side. Seven years later the cough became chronic, with a slight increase in severity during the winter. The sputum produced was usually greenish but occasionally brownish, yellow or white. It varied in amount daily from half a cupful to two cupfuls when an upper respiratory infection was present. Repeated chest x-ray films taken by a physician were reported as showing only bronchitis.

Two years before entry the patient experienced chest pain for the first time. The pain was localized to the right infraclavicular region and persisted as a steady dull ache, but was not made worse by coughing and never interfered with sleep. Concomitantly he also developed moderate hoarseness. A year before entry the patient began to lose weight and strength and a few months later had hemoptysis. Subsequently he continued to raise a little blood-streaked sputum almost every morning. On one occasion he raised almost a tablespoonful of pure blood. Five months before entry he went to a tuberculosis sanatorium because he felt "run down." A chest film was said to have shown healed lesions at both apexes. Nevertheless he was placed on the waiting list and seven weeks before entry entered the sanatorium for observation. While there he gained 3 pounds and felt much improved, although the morning hemoptyses continued. Three weeks later the right infraclavicular pain had almost disappeared, but a similar dull, steady ache developed in the area of the sixth rib anteriorly, immediately to the right of the nipple line. In addition, there were occasional fleeting dull aches over the left chest anteriorly, localized at various points but chiefly near the apex of the heart. A chest tap attempted

at the sanatorium revealed no fluid. No pneumothorax therapy was given. The patient had never had wheezing, pain on respiration, night sweats or exertional dyspnea. During the year before entry he lost 13 pounds despite a good appetite. On leaving the sanatorium he was told that he did not have tuberculosis.

Five years before entry the patient's brother, with whom he had been living, entered a tuberculosis sanatorium, where he ultimately expired.

Physical examination revealed a well developed and well nourished man in no apparent distress. The right middle and lower lobes of the lung were dull to percussion and showed diminished breath sounds and tactile fremitus. A few coarse, moist rales were heard over the same area. There was no tracheal or mediastinal deviation. The heart was normal.

The temperature, pulse and respirations were normal. The blood pressure was 110 systolic, 70 diastolic.

Examination of the blood revealed a red-cell count of 6,480,000, with 75 per cent hemoglobin, and a white-cell count of 17,650, with 81 per cent neutrophils. Repeated sputum smears were negative for acid-fast organisms.

X-ray studies of the chest revealed a mass at the right hilus within which there were several cavities measuring up to 3 cm. in diameter. In the lateral view the mass was seen to occupy the apex of the lower lobe, with the largest cavity lying posteriorly. There was no involvement of the middle and only partial atelectasis of the lower lobe. Slight scarring was seen at both apexes, and there was some thickening in the region of the right costodiaphragmatic angle.

A bronchoscopy was performed.

DIFFERENTIAL DIAGNOSIS

DR. CHARLES L. SHORT To summarize, this patient had a cough of twenty years' duration that began at the age of nineteen. For the first thirteen years this cough was intermittent, occurring in episodes of brief duration and punctuated by an attack of what was said to be lobar pneumonia. During the next five years the cough became continuous and chronic, with a fair amount of sputum, but the x-ray films were said to have shown only bronchiectasis. Two years before entry a new symptom appeared — chest pain, accompanied by hoarseness. In the year before entry constitutional symptoms and hemoptysis appeared, but the x-ray findings were not diagnostic, and it can be assumed that the sputum was negative at the sanatorium. On admission, physical examination showed the patient to be in good condition, without fever, and he had what I assume to be signs of partial bronchial obstruction on the right. Again he had a negative sputum.

We might see the x-ray films at this point.

DR. JAMES R. LINGLEY These are the cavities described lateral to the hilus in the anteroposterior view. In the lateral view they lie posteriorly in the apex of the lower lobe. The cavities are surrounded by considerable density. The whole apex of the lower lobe is involved in this process. This film was taken after tapping the chest, and there is a small amount of air in the pleural cavity, which was not present previously. The diaphragm is possibly a little elevated on the right. The heart shadow is not displaced.

DR. SHORT Is there atelectasis of the right lower lobe?

DR. LINGLEY I think that there is some atelectasis in the apex.

DR. SHORT Is there also a mass in the area of the hilus?

DR. LINGLEY A mass or an area of consolidation.

DR. SHORT Is the mass infiltrating?

DR. LINGLEY Its borders are not at all distinct, but perhaps that is due to atelectasis.

DR. SHORT And you can see no definite mediastinal lymph nodes?

DR. LINGLEY No.

DR. SHORT There are a number of diagnostic possibilities in this case. I might consider what seem to me the unlikely ones first. It does not seem reasonable to explain the whole picture on the basis of bronchiectasis or any usual type of chronic pulmonary infection. One must assume that there was a lesion obstructing the bronchus to the right lower lobe, which was perhaps responsible for the distal pulmonary infection. The absence of mediastinal lymph nodes is against lymphoma with invasion of a bronchus by direct extension. Similarly there is no suggestion of extension into a bronchus from a neoplasm of a neighboring structure, such as the esophagus.

This is not the x-ray picture of sarcoid, and although an infection like actinomycosis can start in a bronchus and cause multiple cavitation, the patient would probably have been sicker, with fever and possibly chills.

Three possibilities therefore remain. The most probable at first glance is carcinoma, that is, a primary bronchiogenic carcinoma. Metastatic lesions that invade the bronchus and simulate primary carcinoma are comparatively rare, and there was no suggestion of a primary lesion elsewhere in the body. The patient had many of the cardinal symptoms of bronchiogenic carcinoma: cough, hemoptysis and dull, nonpleuritic chest pain, although he had no wheezing or dyspnea. There was a mass, if one may call it that, in the region of the right hilus. Cavitation associated with infection distal to such a growth is frequently seen. Hoarseness, not associated with a chest lesion, often indicates cancer, but in this case the lesion seems too low to involve

the nerve supply to the larynx and in any event there is no record of a vocal-cord paralysis. The greatest objection to the diagnosis of primary bronchiogenic carcinoma is the duration of symptoms. The seven-year history of chronic cough seems too long, unless one assumes that the patient had a bronchiectasis of long duration, which was not connected with the lesion that brought him to the hospital. Even the more definite symptoms for two years before admission seem too long not to have produced obvious x-ray and clinical evidence of new growth.

Next tuberculosis must be considered. I meant to ask Dr. Lingley if he saw any evidence of scarring at the apices.

DR. LINGLEY These films, which look very clear to me, do not reveal anything definite at the apices.

DR. SHORT There was a family history of what was probably tuberculosis. The long duration of symptoms suggests pulmonary tuberculosis but not in the face of the negative x-ray films. The repeatedly negative sputum examinations are also against this diagnosis. More than one case of bronchial tuberculosis in this hospital, however, has been diagnosed by bronchoscopy after a negative sputum examination. Still I am forced to reject this possibility and to consider the tuberculosis in this case confusing rather than contributory.

A third possibility is benign tumor of the bronchus. By far the most frequent is the so-called "benign adenoma," which usually occurs in younger people than those with primary carcinoma. Although benign adenoma may be locally invasive and is believed by some to go on to actual malignancy, it grows slowly and is not prone to metastasize. I might mention that in benign adenoma large hemoptyses, with free intervals, are more usual than the repeated slight hemoptyses that this patient had. As an explanation of the cough, I can picture such a tumor's causing long continued irritation and then enlarging to the point of causing bronchial obstruction and distal infection. Perhaps by the time the patient entered the hospital the lesion was actually locally invasive. The relatively good condition of the patient, as well as the symptomatic remission in the sanatorium, is in favor of this diagnosis. I do not believe that a definite diagnosis can be made without the aid of bronchoscopy, but in the light of the whole history benign adenoma presents fewer objections than any other diagnosis.

DR. DONALD S. KING Would you change the diagnosis if you knew that there was one positive sputum examination at the sanatorium?

DR. SHORT That might influence me slightly.

CLINICAL DIAGNOSIS

Carcinoma of lung

DR SHORT'S DIAGNOSIS

Adenoma of bronchus

ANATOMICAL DIAGNOSIS

Epidermoid carcinoma of bronchus (Grade III).

PATHOLOGICAL DISCUSSION

DR KING This was an interesting case. The patient entered Middlesex County Sanatorium with a diagnosis of pulmonary tuberculosis. There was a positive family history in the case of the brother, and the early x-ray films of the patient showed a lesion in the right upper lobe that was not visible in the films displayed here. The lesion at the right hilus, which was seen in these films, was not present when he was first admitted to the sanatorium but was demonstrable after a four-month period, during which moist and musical rales over the right mid-chest in front also developed. The signs and the x-ray findings were observed at the time when Dr Lowrey Davenport was first looking for indications for bronchoscopy in patients with tuberculosis at the sanatorium, and this was the first patient whom he bronchoscoped there. The findings were so striking that he had no difficulty in selling the procedure to the sanatorium doctors in later cases. In this case the tumor mass was so large and friable that a large section was actually coughed into the bronchoscope at the time of its introduction.

Do you want to divulge the diagnosis that was made on that bronchoscopic specimen, Dr Mallory?

DR TRACY B MALLORY The tumor was a highly malignant carcinoma, probably epidermoid in type.

DR KING Because of this finding, a total pneumonectomy was performed. I believe that, so far as the records of the Massachusetts General Hospital are concerned, this is one of two patients who are now living five years after a removal of a lobe or entire lung for bronchiogenic carcinoma. The patient has been under observation in the hospital recently because of an acute infection in the remaining lung. He recovered satisfactorily.

DR MALLORY He now has survived nine years.

DR SHORT Were there positive lymph nodes in the hilus?

DR MALLORY No. The tumor was at the junction of the middle-lobe and the lower-lobe bronchus. It was an ulcerated lesion, nearly 2 cm in diameter, and the histologic appearance was that of a highly malignant tumor. This is the last case on which I should have given a favorable prognosis, and strangely enough the patient presents our best result.

DR KING Perhaps the fact that the diagnosis was made the sigearly is nificant point in this case. The symptoms, signs and x-ray findings were discovered

at an early date, because he was in the sanatorium during this period.

DR SHORT You assume that the previous symptoms were due to tuberculosis?

DR KING I do not know just how many of the symptoms were due to tuberculosis, but I had understood that the surgical specimen showed not only cancer in the right lung but also a tuberculous cavity. We have therefore always spoken of this case as a combination of both tuberculosis and carcinoma. I may be wrong in my memory of the pathologist's report on the surgical specimen.

DR MALLORY We have no record of tuberculosis.

CASE 32332

PRESENTATION OF CASE

First admission. A forty-three-year-old Chinese laundryman entered the hospital because of persistent cough with hemoptysis.

The history was not easy to obtain, because of language difficulties. The patient was apparently well until a year and a half before admission, when for the first time he coughed up about a cupful of blood. Subsequently he continued to have hemoptyses at irregular intervals varying from one to several weeks. The cough was worse in the morning, during the winter months and in the presence of upper respiratory infection. Occasionally it was accompanied by a sharp pain in the left epigastrium. The appetite became poor, and during a period of four months the patient lost about 8 pounds. There was no weakness or fatigue. Fifteen months before admission, the patient was seen in the Out Patient Department. An x-ray film of the chest at that time revealed increased density in the region of the lingula and both lower lobes. The left lower lobe appeared to be nearly completely collapsed in the basilar segment, but the dorsal division did not seem to be involved. Within the collapsed lobe there were dilated bronchi. There was also beginning dilatation of the lateral division of the lingular bronchus of the left upper lobe and of the anteromedial bronchi of the middle lobe, as well as the anterior division of the right lower-lobe bronchus. Bronchoscopy showed moderate hemorrhagic bronchitis of the left lower lobe, with questionable bronchiectasis. Repeated sputum smears were negative for acid-fast organisms. Twelve months before entry, the patient entered a state hospital because of the continued cough and hemoptyses. He remained there until his admission to this hospital. Serial sputum examinations had shown no tubercle bacilli.

The patient gave no history of tuberculosis or exposure to it. He had had an attack of "pneumonia" as a young man.

Physical examination revealed a well developed and well nourished man in no acute distress and coughing only infrequently. The sputum, however, was foul and contained frothy blood-tinged material. Percussion of the chest revealed some dullness at both bases posteriorly and slight dullness below the right axilla. There were coarse rhonchi in the right upper chest posteriorly and also a few on the left. Breath sounds seemed slightly diminished over the right chest anteriorly and laterally. The heart and abdomen were normal. The tendon reflexes of the left arm were somewhat hyperactive, and there was some weakness and flabbiness of the left hand. The fingers of both hands showed early clubbing.

The temperature, pulse and respirations were normal. The blood pressure was 120 systolic, 80 diastolic.

Examination of the blood showed a red-cell count of 4,600,000, with 11.3 gm of hemoglobin, and a white-cell count of 6600, with 71 per cent neutrophils and 19 per cent lymphocytes. The total protein was 8.2 gm per 100 cc. The urine was normal.

X-ray examination of the chest, including bronchograms, showed no change from the previous findings, the most marked bronchiectatic process being in the left lower lobe.

The patient was discharged on a high-protein diet.

Second admission (three weeks later). The patient was readmitted for surgery. Since discharge he had continued to cough up daily about 100 cc of foul, gray sputum, but there had been no further hemoptyses. Physical and laboratory findings were essentially the same as on the previous admission. The patient was placed on aerosol penicillin to reduce the amount of sputum. On the fourteenth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR REED HARWOOD. The diagnosis in this case involves a discussion of the causes of bronchiectasis. Bronchiectasis may be defined as a chronic progressive disease of the bronchi, with bacterial invasion of the bronchial wall and the surrounding lung tissue. It results in an inflammatory reaction of the bronchial wall, dilatation of the bronchus and varying degrees of inflammatory reaction and fibrosis of the adjacent lung. Different sorts of mechanical forces are said to account for the bronchial dilatations. For example, in the presence of obstruction of a bronchus, coughing increases not only the intrabronchial pressure distal to the obstruction but also the difference between the intrapleural and the intrabronchial pressure with each inspiration. It is believed that most cases of bronchiectasis are caused by obstruction of the involved bronchus as well as by infection. The infecting organisms may be any of the pyogenic bacteria, as well as spirochetes and fusiform bacilli, the tubercle bacillus and other less frequent organisms. The

usual sequence of events in the development of bronchiectasis is repeated attacks of bronchitis, often associated with chronic sinusitis. Unresolved pneumonia or repeated attacks of bronchopneumonia may also initiate the process. In the case under discussion it seems probable that the bronchiectasis had its beginning when the patient had pneumonia as a young man. The history of chronic cough, which was worse in the morning, during the winter and during respiratory infections, is typical, as is the character of the sputum, the periodic hemoptyses and the clubbing of the fingers. Indeed, there is little in the record to suggest that this case does not fall into this category. I believe that the patient was prepared for left lower lobectomy with this diagnosis in mind.

Some of the other conditions that cause bronchiectasis must be considered. Tuberculosis was obviously suspected in this case. Repeated failure to find tubercle bacilli in the sputum is strong evidence against this diagnosis. It is extremely probable that while the patient was at the State Hospital the stomach contents were examined for tubercle bacilli. Tuberculosis most frequently involves the apexes of the lungs, but its absence in these areas does not exclude it from consideration. A tuberculous ulceration of the lower main-stem bronchus, however, would probably have produced a rapid spread of the disease and a downhill course. A tuberculous stenosis in this region would have been visible to the bronchoscopist. The involvement of bronchi going to several lobes is against a localized tuberculous lesion.

Could a tumor have caused the bronchiectasis? Benign and malignant intrabronchial tumors cause obstruction to the bronchus with infection beyond the obstructed area, as do tumors of mediastinal lymph nodes and infected lymph nodes. One would expect, however, to find the bronchiectasis confined to the involved segment. Besides, the bronchoscopist would be able to see the obstructed area. The same reasoning applies to the presence of a foreign body in the bronchus.

Much rarer causes of bronchiectasis are actinomycosis and other mycotic infections. I assume that the presence of sulfur granules or yeast cells would have been detected in some of the many sputum examinations. In actinomycosis the constitutional symptoms are apt to be severe, and there is a tendency to sinus formation and particularly to abscesses that drain through the chest wall.

Mention is made of increased reflexes in the left arm, with weakness and flabbiness of the left hand. Without more precise neurologic findings, it is difficult to connect this observation with the pulmonary disease, especially since the lesions in the lung were too low to have produced symptoms of brachial plexus. Metastases of tumor could, of course, account for such a finding, but I do not consider the data sufficient to make a definite diagnosis.

In summary, I believe that this patient had bronchiectasis as a result of repeated upper respiratory and bronchopulmonary infections. Tuberculosis is my second choice, but there is little evidence to support this diagnosis. The diagnosis of tumor or other unusual causes of bronchiectasis remains in the realm of speculation.

CLINICAL DIAGNOSES

Bronchiectasis

DR HARWOOD'S DIAGNOSIS

Bronchiectasis of left lower lobe

ANATOMICAL DIAGNOSES

Bronchiectasis of left lower lobe.

Pulmonary tuberculosis

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY: This patient was operated on with a preoperative diagnosis of bronchiectasis, as Dr Harwood suggested, and a lobectomy was done. The presence of extensive bronchiectasis was confirmed, but no obstruction of the major bronchi was found. There was a marked chronic inflammatory process in the lung parenchyma as is often present in cases of bronchiectasis, and the one surprise was that scattered through this inflammatory tissue were nodules of tuberculous infection. Most of these were fairly well healed, but one or two still had frankly caseous centers, a few giant cells and some probable degree of activity, although I am inclined to believe that the tuberculosis was coincidental and not responsible for the primary lesion, which was certainly bronchiectasis.

DR DONALD S KING: You have not often found tuberculosis in lobes that have been removed?

DR MALLORY: Very seldom indeed.

STATUS OF NATIONAL HEALTH LEGISLATION

THE stormy seventy-ninth session of Congress has terminated without the enactment of proposed health legislation, which has been surrounded with controversy and recrimination since the first committee hearings. Proponents of the Wagner-Murray-Dingell Bill have postponed their efforts to obtain enactment until Congress reconvenes in January, 1947, and the Pepper Bill has not been reported out of committee.

A respite is thus granted in which the medical profession can marshal its forces for the fight when these bills come up for consideration during the eightieth session of Congress. Organized medicine also has an

opportunity to initiate action that will make the threatened legislation unnecessary.

Senate Joint Resolution No 177, introduced by Senators Pepper and Taft on instructions from the Senate Committee on Education and Labor, fills a need that has been greatly felt and also demonstrates what may be a healthy trend away from the type of governmental control and participation embodied in the Wagner-Murray-Dingell and Pepper bills. The resolution amends the Social Security Act to provide for increased grants to the states for crippled children, maternal and child health and child welfare, favorable action on the resolution — which has still to be considered by the Senate Finance Committee and the House Appropriations Committee — would establish over the funds concerned regulations and controls similar to those already in effect on appropriations for the Children's Bureau. Legislation that takes the form of badly needed aid for existing welfare agencies — rather than that of creating a spate of new bureaus and extending regimentations and control to fields that should be beyond the concern of the Government — is always welcome.

Another encouraging note is provided by Senate action on President Truman's reorganization plan, which transfers the Children's Bureau from the Department of Labor to the Federal Security Agency and thus affords an opportunity for co-ordination between the Bureau and the United States Public Health Service and similar agencies.

NEW ANTIMALARIAL DRUGS

DURING the past eight months, the discovery of two new antimalarial drugs has been announced. One, called "paludrine" (M 4888), was produced in England,^{1 2} and the other SN 7618, which was later called "chloroquine," was developed in this country and announced by the Board for the Co-ordination of Malarial Studies.^{3 4} Both drugs are the result of extensive efforts on the part of British and American scientists during World War II to find new chemotherapeutic agents for the prophylaxis, suppression and treatment of malaria.

The initial and urgent need for an extensive research program on the chemotherapy of malaria arose out of the grave problem of malaria control and treatment among the armed forces in World War II. The loss of the main source of cinchona bark for the production of quinine and the questionable value of quinacrine (Atabrine) furnished the driving force for research into the fundamental facts about malarial parasites, the disease that they produce and the chemotherapy of the disease. The achievements and value of the program are now becoming apparent.

Aside from the fundamental information that helped define the problems involved in suppressing and curing malaria, over fourteen thousand compounds were tested for their activity against avian malaria in this country and eighty of these compounds were subsequently tested on cases of human malaria. In addition, over one thousand compounds were made and tested in England.⁵

Coincident with this vast search for new effective drugs, experimentation with quinacrine proved that different dosage schedules, employing larger doses, were needed to produce and maintain effective plasma levels for suppression and treatment.⁶ This information helped to explain previous difficulties with the drug. The new dosage schedules caused a dramatic reversal in the trend of malarial incidence among the armed forces. Malaria could be suppressed, and a radical cure of falciparum malaria could be effected, but quinacrine continued to fail as a true casual prophylactic and as a radical cure for relapsing vivax malaria, particularly with strains of Pacific origin. Although the new quinacrine therapy was of strategic value in winning the war, the search for more effective drugs continued.

The reasons for the failure of quinacrine and quinine to produce radical cures of vivax malaria

and to prevent the relapsing nature of the disease in a majority of cases are slowly becoming understood. These drugs are effective against all stages of the parasites in the blood stream, but they are apparently unable to penetrate other cells and thus to sterilize the more or less hypothetical tissue stage of the plasmodia. These tissue stages, which develop from the sporozoites injected by the infective

mosquitoes prior to invasion of the blood stream and the erythrocytes, have been seen and studied in several types of avian malaria.⁷ The experiments of Fairley⁸ and his collaborators suggest that they also exist in human malaria. Thus an effective drug must presumably penetrate selectively and exert a lethal effect on the parasites within the cells of such organs. This process appears to be

necessary for true casual prophylaxis, radical cure and the prevention of relapses.

With the above information, the English scientists decided to explore some new ring system that would satisfy the requirements for antimalarial activity against the tissue stages of the parasites.⁹ Compounds known as pyrimidines were chosen for the initial studies because of their physiologic importance in the synthesis and function of cell nuclei. That this choice was a fortunate one was soon verified by the discovery of antimalarial activity in a derivative of anilino-pyrimidines called "2666."

The evolution of paludrine from 2666 is an exciting account⁹ and a prime example of the type of achievement made possible by a closely co-ordinated collaboration between scientists from different fields. It is sufficient to say here that paludrine is N_1 -p-chlorophenyl- N_4 -isopropyl biguanide and that the compound is "a chemical type not hitherto met with in chemotherapy."⁸ The antimalarial activity of this drug initially demonstrated in cases of human malaria in England has been substantiated by field

trials at Cairns, Australia^{10, 11} The drug has been shown to be a true casual prophylactic and to produce a radical cure of malignant tertian malaria. With vivax malaria, paludrine is a partial casual prophylactic, tests regarding radical cure were not completed, but a dosage of 0.1 gm twice a week appeared to prevent relapses indefinitely. Furthermore, the difference between the therapeutic and the toxic dose was found to be great enough to permit a wide latitude in therapy without danger to the patient.

Although detailed accounts about the discovery and therapeutic trials of chloroquine have not appeared, the story of this new antimalarial drug is probably just as fascinating. Here again, falciparum malaria is cured radically but vivax malaria is more resistant to treatment. The primary attributes appear to be the small dosages that are effective in producing radical and clinical cures, it has approximately three times the antimalarial activity of quinacrine and causes no discoloration of the skin.⁴ Since this drug has been tried on over 5000 cases of human malaria, judgment concerning its efficacy rests on firmer ground than does that for paludrine. Reports of well controlled field experiments comparing the simultaneous effects of the two drugs will, however, be awaited with great interest.

Those who know the malarial problems awaiting control and eventual solution are well aware that the existence of two new drugs cannot achieve the desired results. The combined efforts of governments, peoples and specialists in malariology utilizing drugs, antianopheline campaigns and new insecticides are needed for effective malaria control.

MASSACHUSETTS MEDICAL SOCIETY

DEATH

MESERVE — Faith L. Meserve, M.D., of Weston, died July 19. She was in her fifty-second year.

Dr. Meserve received her degree from Boston University School of Medicine in 1926. She was a fellow of the American Medical Association.

Her mother, two sisters and a brother survive.

MISCELLANY

DR. JOHN E. FISH — AN APPRECIATION

Massachusetts has long taken pride in its pioneering leadership toward social improvement and cultural achievement. Here in Massachusetts John Harvard founded the first college. In later generations, Horace Mann fathered public-school education as it is known today, Dr. Samuel Howe organized the Perkins Institute for the Blind, and Laura Bridgman and Helen Keller, without sight or hearing, gained liberal educations. In line with these traditions, the excellent St. Botolph Street School for Crippled Children was founded for the purpose of extending education to children whose physical disabilities prevented their attending the regular schools. It soon became apparent, however, that a day school could not meet the full requirements for educating all the cripples in the Commonwealth. In 1904, the Massachusetts Legislature therefore created a novel institution to serve as a public boarding school, with hospital facilities available to all disabled children, whether rich or poor.

The opening of the Hospital School was delayed for four years while land was purchased and the first buildings erected. During this interval, one of the greatest difficulties had been to find a man qualified to serve as superintendent. In 1908, by rare good fortune, the trustees selected Dr. John E. Fish for this difficult post, and nowhere could they have found a man better qualified for these new and untried duties. Born in Vermont, the son of a country doctor, he was already steeped in the fine traditions of the medical profession, to which he added his own liberal education at Dartmouth College and Medical School. He had gained administrative experience in some of the state institutions and had acquired a clear insight into human character through the patients he dealt with there. More fortunate still, Dr. Fish was blessed with a wife ideally suited to help in the life of such a school as this. She was the daughter of a Civil War surgeon who spent his later years in family practice in Vermont. With her refinement, quiet humor and unfailing cheerfulness, she brought to her husband the help that a man needs most under difficulties. Thus Dr. Fish was the perfect choice in every respect, to face the unforeseen problems and difficulties of the new institution. Time has tried him for thirty-eight years, during which he has carried the school through good times and bad, through the upheaval of two world wars and into the second postwar era. Without a break in his long service, he has been reappointed by governors of both major political parties. He has outlived the members of the original Board of Trustees who founded the school and has served under the chairmanship of the son of one of them, the sons of three of the doctors on the earlier consulting staffs have taken the places of their fathers beside him. From the beginning and without faltering, he has fulfilled and advanced the highest hopes of those who first conceived of the institution. As one of the present trustees has remarked: "The school was merely a dream when it was planned. Fish has made that dream come true."

The extent of his achievement in giving reality to such a dream can be measured only by the lives it has liberated from crippled helplessness into the freedom of self-supporting and educated citizenship. It is difficult to appreciate the neglect of educational opportunities for handicapped children during the early years of this century. In the beginning, the school's admissions included many children who had grown into adolescence without a single day's schooling. At the age of fourteen and fifteen, these boys and girls were given their first lessons in elementary reading and writing. Every form of disability was represented among the applicants, but no

matter how completely helpless the child appeared physically, none were denied the opportunities of learning provided they had the capacity to understand. One girl, who was born without hands went to the school at the age of four. After graduation from the eighth grade, she took a stenographic course and learned to write shorthand at a rate of one hundred and twenty words a minute. She has gone on to the study of art and has painted some creditable portraits. This girl is only one of the many whose physical handicaps would have seemed totally disabling in any other locality but whose development at the school has been possible. They came as children with useless limbs and twisted backs, or confined to crutches and wheel chairs or with halting, unbalanced gaits or perhaps unable to get off a litter. But they acquired the spirit of strength and independence, the will to do for themselves, and they left equipped with knowledge equivalent to that of any normal children in similar grades. In all, there have been six hundred and forty-one graduates of the school, a large number of whom have become self-supporting and many of whom are raising and supporting their own families. Most of them have found specialized jobs of one type or another. Some, however, have carried their education on into further fields. Thus, two have won seats in the Legislature, two are artists, two are lawyers, one a doctor, another a nurse and still another a social worker. Seven of them have returned to serve on the staff of the school—one as treasurer, and one as head of the school department. Seven outgrew their physical handicaps and served in the armed forces during the war.

Three general ideas that have formed the basis of Dr Fish's program can best be described by quotation of his own terse phrases. The first of these is the declaration; "Education of a crippled child is not a charity any more than the education of a normal child." One might say that such a statement seems self-evident, yet it was not always so regarded, nor has any state in the Union other than Massachusetts gone to such lengths in giving this thought practical fulfillment. In the early years of the school, a well meaning critic once objected that money spent on the education of a crippled child would be wasted unless the child could be made self-supporting. To this objection, one of the school's founders replied "That is not the way our Saviour looked at it. He said, 'Give life, and give it more abundantly.'" Throughout his career, Dr Fish has clung to that doctrine, and it is suitably inscribed on the memorial clock tower that the graduates have dedicated to him.

As a second principle, Dr Fish believes, "No form of surgical care or other treatment can be regarded as complete that neglects the social, moral and mental growth of the child." This statement clearly exposes the most serious defect in other programs for crippled children: too many private, state and federal institutions offer only operative or postoperative surgical treatment, not recognizing that partial correction of a physical deformity still leaves a crippled mind and not realizing that in the months, and often the years, spent in clinics and hospital wards and convalescent centers, the child loses invaluable time both from textbook lessons and from character-building experience. Such lessons and such experience must come early enough to help the child develop the right mental attitude, if they are postponed too long, the damage to the child's mental processes may be irreparable. As the trustees observed in their first report "Disabled children who have been too tenderly cared for much beyond the age of puberty are liable to develop a lack of initiative and indolence that is difficult to overcome. A pauperization of character has been developed." The ideal of the Hospital School has therefore been to allow education, surgical care and convalescence to proceed together—and note that education is given first place.

Perhaps the most important basis of the school's success is explained in Dr Fish's third and vital maxim, "It has been found that the placing of crippled children under healthful conditions, thus directly stimulating opportunities for play, study and amusement, tends to destroy any source of self-pity and teaches them to minimize or forget their disabilities." By this concept, the role of education is extended beyond ordinary schoolbook instruction and reaches a personal, psychologic, almost spiritual perspective. It aims at improving character, so that these children may grow to a richer, more self-sufficient maturity. That, essentially, is what the Hospital School has succeeded in doing with the invalids who are enrolled as students. For the fulfillment of

this purpose, it was recognized that even crippled children are dominated by normal cravings for games and social activities, and that such activities constitute a necessary part of their development. There is not space to describe the numberless methods, large and small, that Dr Fish employed to carry his thought into action. One example will serve to illustrate the rest. This was the organization of a baseball team on which each boy was allowed to play so far as his own abilities permitted. The legless pitcher, who trained himself to strike out normal boys of the local schools, will always be remembered, as will the batter with artificial legs who was supplemented by an armless boy running bases. No matter how the score stood with their rivals, such teams defeated their own disabilities, which were their real opponents. The same principle was carried to all the school's activities. Musical talents were cultivated by choir singing and by the organization of a school band. A shop for watch repairing under the tutelage of an expert craftsman has been eagerly attended. The dormitories were made as home-like as possible, and the girls were encouraged to help in cooking and serving meals. The girls of the senior class were given a beautifully furnished reception room, where they served afternoon tea once a week to guests and callers. The local clergy have co-operated, and Catholic, Protestant and Jewish services are held at the school every week. Thus, so far as possible, the children learn to lead normal lives in an optimistic, healthful and happy environment.

Based on these principles, the Hospital School has become a permanent institution in the life of the Commonwealth. It is still unequalled and unrivaled anywhere else in the world. Its traditions are now so well established that one can look forward to another generation of service on a level with what it has already produced. Now, as he retires from his duties, one feels more keenly than ever gratitude and appreciation for Dr Fish's high-minded vision and for the devoted service and strong and wise leadership that made a dream come true.

NOTICES

ANNOUNCEMENTS

Dr H Myer Bloomenthal announces his return from military service and resumption of practice of medicine and surgery at 1396 Commonwealth Avenue, Boston

Dr Leon Ryack, having returned from military service announces the opening of his office for the practice of medicine at 1755 Beacon Street, Brookline

Dr Maurice M Tolman has returned from naval duty and will resume the practice of dermatology at 636 Beacon Street, Boston

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY

The next written examination (Part I) of the American Board of Obstetrics and Gynecology for all candidates will be held in various cities of the United States and Canada on Friday, February 7, 1947, at 2:00 p.m. Candidates who successfully complete this examination proceed automatically to the Part II examination held later in the year. All applications must be in the office of the Secretary by November 1, 1946. Candidates in military service are requested to keep the Secretary's Office closely informed of changes in address.

A number of changes in Board regulations and requirements were put into effect at the last annual meeting of the Board held in Chicago from May 5 to May 11, 1946. Among these is the requirement that case records must now be forwarded to the Secretary's Office from thirty to sixty days after the candidate has received notice of his eligibility for admission to the examinations for certification. At this meeting the Board also ruled that it will not accept a nine-month residency as an academic year toward years of training requirements following the termination of the official period of intern and residency acceleration (April 1, 1946).

Applications are now being received for the 1947 examinations. Final examinations will be held in Pittsburgh June 1 to 7, 1947. For further information and application blanks address Paul Titus, M.D., Secretary, 1015 Highland Building, Pittsburgh 6, Pennsylvania.

ACUTE GENERALIZED MILIARY TUBERCULOSIS IN ADULTS*

A Clinicopathological Study Based on Sixty-Three Cases Diagnosed at Autopsy

CARLETON B. CHAPMAN, M.D.,† AND C. MERRILL WHORTON, M.D.‡

BOSTON

ACUTE generalized miliary tuberculosis is a condition that results from the sudden and often overwhelming hematogenous dissemination of tubercle bacilli from an established focus to many of the organs of the body. The large number of small, acute tubercles that develop in these organs have been said to resemble millet seeds in size and appearance, whence stems the adjective "miliary." The clinical course is so varied that diagnosis before death is often not achieved. The condition should be rigidly differentiated from the various forms of nonprogressive or slowly progressive, more or less localized forms of disseminated tuberculosis. The hematogenous dissemination of occasional tubercle bacilli from chronic foci in the lungs or elsewhere frequently results in the various forms of chronic disseminated tuberculosis so often seen at autopsy. Pennington¹ found that 68 per cent of 200 cases of pulmonary tuberculosis at autopsy showed extrapulmonary foci of a chronic type, lesions that Krause² terms "benign generalizations" of pulmonary forms of tuberculosis. Hegler³ points out that when occasional tubercle bacilli are released, producing isolated tubercles in one or two additional sites, the disease has in a sense become generalized but is still quite distinct from acute generalized miliary tuberculosis. Kayne, Pagel and O'Shaughnessy⁴ believe that acute, fatal disseminations occur in an extremely small percentage of affected persons but that some 40 per cent show evidence of hematogenous dissemination at autopsy. Most of the cases fall in the group that these authors term "abortive hematogenous dissemination," and the extrapulmonary lesions are generally nonprogressive.

One must recognize, therefore, that disseminated tuberculous infection may appear in several forms. One extreme is the acute, progressive disease, which is the subject of this survey, the other extreme is the

chronic, nonprogressive extrapulmonary tuberculous lesion, which seldom, if ever, causes death.

All the autopsy reports for the Boston City Hospital over a five-year period (1937-1941, inclusive) were reviewed. In selecting cases for the series, two important exceptions were made, as follows: none of the autopsy material from the Sanatorium Division was utilized, and cases in patients less than twelve years of age were excluded owing to the fact that the autopsy material included a disproportionately small number of children. We have thus concerned ourselves exclusively with the condition as it occurred in adults in this, a general, hospital.

INCIDENCE

General

Acute generalized miliary tuberculosis is generally considered to be a rare condition. Lewison et al.⁵ reported that 1.09 per cent of 8800 consecutive autopsies at Cook County Hospital showed the condition. Our own data indicate that 1.55 per cent of the 4066 cases autopsied at the Boston City Hospital between 1937 and 1941 showed acute generalized miliary tuberculosis. Of considerably greater interest is the frequency with which the condition is present in cases showing some more chronic type of tuberculosis. Fishberg⁶ states that of patients suffering from pulmonary tuberculosis in any of its forms, about 1 in 20 dies with symptoms of miliary dissemination of tubercle bacilli, and approximately the same figure is given by Simmonds.⁷ In Lewison's series the condition was found in 11.9 per cent of tuberculous cases. Auerbach⁸ reviewed 1656 consecutive autopsies on patients with tuberculosis, in 17.9 per cent of which acute generalized miliary tuberculosis was demonstrated. We reviewed autopsies on 4066 patients, in 310 of which (7.6 per cent) tuberculosis of some sort was present. In this group of 310 cases, there were 63 cases of acute generalized miliary tuberculosis (20 per cent). Our figures are somewhat analogous to Lewison's in that they represent the incidence of the condition at

*From the Thorndike Memorial Laboratory, the Second and Fourth Medical Services (Harvard), the Mallory Institute of Pathology, Boston City Hospital, and the Department of Medicine, Harvard Medical School.

†Assistant in medicine, Harvard Medical School.

‡Formerly first assistant in pathology, Boston City Hospital.

autopsy in a general hospital, but they are not truly analogous in that owing to the nature of the autopsy material children have been excluded from the series

By Sex

Litten,⁹ in one of the classic articles on the subject, stated that acute generalized miliary tuberculosis is more frequent in men than in women, and Fishberg⁶ is in agreement. Hartwich,¹⁰ however, reviewing 200 cases of the disease, found that 51 per cent of the patients were females and 49 per cent were males. In our series of 63 cases, there were 44 men (70 per cent) and 19 women (30 per cent). Of the 310 patients in whom some type of tuberculosis was found at autopsy, however, 69 per cent were males and 31 per cent were females. Hence the sex incidence of acute generalized miliary tuberculosis in this series is not significantly different from that for tuberculosis of all types. Furthermore, in this hospital more autopsies are permitted on men than on women, and we are of the opinion that the alleged sex difference in the incidence of the condition is more apparent than real.

By Age

That the disease may occur at any age is generally agreed. Its occurrence in the earliest weeks of life has been noted by Hegler,³ who reviewed the cases of this type reported up to 1923. Transmission of the infection to the unborn child by the maternal and placental circulations has been suggested, and we noted 1 case in which such a process may have occurred.

The highest incidence of the disease is said by some authors^{3, 8, 11} to occur in the second and third decades. In Hartwich's¹⁰ series the peak incidence

incidence of nonmiliary forms of tuberculosis at the Boston City Hospital, which, surprisingly enough, was in the seventh decade. Our findings are not necessarily at variance with the statements by Hartwich and by Amberson, since no children were included in this series. Among adults, however, the disease was more frequent in the younger than in the more advanced age groups.

It is of interest to note that although peak incidences occurred as indicated, acute generalized miliary tuberculosis is by no means unknown in the seventh, eighth and ninth decades. Thirteen per cent of Hartwich's and 14 per cent of Braun's¹² patients were over sixty years of age. Thirty per cent of our patients were over that age, and 16 per cent were over seventy years of age. The oldest patient was eighty-five and the youngest nineteen.

CLINICAL ASPECTS

Diagnosis

In this series the ante-mortem and post-mortem diagnoses of tuberculosis were as given in Table 2.

TABLE 2 Clinical Diagnosis and Findings at Autopsy

DIAGNOSIS	DIAGNOSED CLINICALLY	FOUND AT AUTOPSY
Fibrocasseous pulmonary tuberculosis	36	45
Acute generalized miliary tuberculosis	16	63
Tuberculous meningitis	7	7
Tuberculosis of larynx and pharynx	6	2
Tuberculous cervical adenitis	5	—
Tuberculous peritonitis	4	4
Tuberculosis of gastrointestinal tract	4	27
Tuberculosis of bone	2	4
Tuberculosis pericarditis	2	4
Tuberculosis of epididymis	1	4
Tuberculosis of kidney	1	6
Tuberculosis of testicle	1	1
Tuberculous pancreatitis	1	1

In this hospital, the larynx, pharynx and cervical lymph nodes are not routinely examined at autopsy, so that figures for these sites are probably artificially low. The large discrepancy between the clinical and the pathological diagnosis of gastrointestinal tuberculosis is probably due to the obscurity and relative unimportance of the associated symptoms.

As shown, the ante-mortem diagnosis of miliary tuberculosis was made in 16 of the 63 cases (25 per cent), and 2 additional cases were tentatively so diagnosed. A survey of these 16 cases disclosed that the majority were diagnosed on the basis of x-ray examination of the chest. Several cases, however, were apparently diagnosed largely on the basis of the clinical course, the presence of known chronic tuberculosis and the leukocyte picture. Our diagnostic average compares rather unfavorably with that reported by Lewison,⁵ who apparently found that 75 (78 per cent) of the 96 cases of acute generalized miliary tuberculosis demonstrated at autopsy at Cook County Hospital were diagnosed clinically.

TABLE 1 Age Incidence of Acute Generalized Miliary Tuberculosis and of Nonmiliary Tuberculosis Among Adults at Autopsy*

AGE	TOTAL CASES WITH NONMILIARY TUBERCULOSIS		TOTAL CASES WITH MILIARY TUBERCULOSIS	
	NO.	PERCENTAGE	NO.	PERCENTAGE
15-19	2	—	2	3.2
20-29	10	4.5	13	20.6
30-39	24	9.7	7	11.1
40-49	39	15.8	11	17.5
50-59	46	18.6	11	17.5
60-69	55	22.0	9	14.3
70-79	46	18.6	9	14.3
80-89	10	4.5	1	1.5
90 and over	1	—	0	—
Unknown	14	5.5	0	—
Totals	247		63	

*Chi square = 23.0, when N = 5. P = less than 0.01.

occurred in the first decade. Amberson¹³ states that acute generalized miliary tuberculosis occurs most frequently in babies and young children. In the present series, the peak incidence (Table 1) was found in the third decade. In contrast is the peak

History and Symptoms

A history of exposure to active tuberculosis was obtained in 16 per cent and a history of previously active tuberculosis in 26 per cent of the 35 cases in which specific inquiry was made.

Anorexia, weight loss and cough were the most prominent symptoms, occurring in 90, 85 and 82 per cent, respectively. Night sweats, dyspnea, chest pain and hemoptysis were recorded in 79, 64, 49 and 15 per cent, respectively. Any or all of these symptoms may occur in fibrocaceous pulmonary tuberculosis without miliary dissemination and did not, for this reason, serve to establish the correct diagnosis in any of our cases. In several cases, however, the rapidity of onset and the severity of symptoms appear to have been of assistance in arriving at the correct diagnosis. Dyspnea was not significantly more frequent in the group of cases that showed massive involvement of the lungs by the miliary process than it was in the group that did not. Hemoptysis was seen in 6 cases of the entire series, and in 5 of these chronic pulmonary lesions as well as miliary involvement of the lungs were present at autopsy. Cough was equally prominent in both groups. Pronounced dyspnea was usually seen as a terminal finding but apparently provided little or no specific diagnostic assistance.

Seven patients presenting neurologic signs and symptoms were diagnosed clinically as having tuberculous meningitis, and the diagnosis was confirmed at autopsy in all. This incidence (11 per cent) is lower than that reported by most authors, probably because children were excluded. It is generally agreed that the more children included in any series, the higher the incidence of tuberculous meningitis.^{3, 11, 14}

Physical Findings

Physical findings in acute generalized miliary tuberculosis are seldom of much diagnostic assistance. In many of these cases, physical examinations were necessarily cursory and incomplete, and in only 1 case was a physical finding diagnostic (see below).

The course of the temperature in the disease was described by Cornet¹¹ as having no definite form and showing irregularity as its most characteristic feature. Hegler³ found true hectic fever of the so-called "picket-fence" type and continued typhoid fever in some of his cases, but stated that the irregular remittent type was the most frequent. The latter type is characterized by irregular and unpredictable rises of temperature to 102 or 103° F every few days, the temperature falling to lower but not to normal values between rises. Afebrile cases are described by most writers, and are said in the older literature to occur most frequently when such complications as tuberculous meningitis, cardiac insufficiency or extreme age are present. After a careful survey of the temperature charts in this series we find ourselves

in complete agreement with Cornet. We could find no feature that was common to the entire group, and many of the charts were so irregular as to defy classification, although about one third of them fit roughly into the irregular remittent category. True "picket-fence" charts were noted in 4 cases, and *typus inversus* charts in 3. The highest temperatures in the entire series were found in one of the cases of *typus inversus* temperature, the maximum reading being 107° F. All 7 of the cases in which tuberculous meningitis was found showed elevated temperatures, and no such depression of temperature as has been frequently described in the past was found in the group.

Rapid pulse rates were the rule, and tachycardia out of all proportion to the temperature was seen in many cases. Sixty per cent of the patients had sustained pulse rates of 120 or higher, and terminal elevations to 160 in association with terminal tachypnea were frequent.

A pronounced increase in the respiratory rate has been thought to indicate diffuse miliary involvement of the lungs.³ An attempt to correlate rapid respiratory rates with miliary involvement of the lungs in this series met with complete failure, and we doubt that the segregation of a clinical group as pulmonary miliary tuberculosis on the basis of marked increase of respiratory rate is justified. Sustained elevations of the respiratory rate to 30 or higher were present in 60 per cent of the series, and terminal tachypnea associated with cyanosis was present in almost all the patients.

The general appearance of most of the patients was consistent with that seen in any acute febrile illness. The state of nutrition on entry to the hospital was given as poor in 62 per cent, good in 25 per cent and excellent in 8 per cent. It is interesting to note that several patients were frankly obese but lost weight rapidly during the relatively short course of the disease.

Clubbing of the fingernails was noted on physical examination in 4 cases, 2 of which showed fibrocaceous pulmonary tuberculosis, on which pulmonary miliary involvement was superimposed. In the other 2 cases the lungs at autopsy showed miliary lesions but no chronic tuberculous involvement, suggesting that clubbing is not necessarily dependent on chronic pulmonary changes but may be produced by acute miliary involvement of the lung alone.

Ophthalmoscopic examination disclosed the presence of miliary tubercles of the ocular fundi in 1 case. This observation represents the only physical finding in the series that was diagnostic of acute generalized miliary tuberculosis. Several authors, including Litten,⁹ state that miliary involvement of the ocular choroid is a frequent occurrence. Choroidal tubercles are said to be bilateral and to appear as pale, grayish-white oblong patches with indistinct edges. In the early stages, the di-

iameter of such tubercles seldom exceeds 1 mm. When caseation takes place, a central depression may develop in the lesion.³ Although such tubercles may be confused with other ophthalmoscopic findings, their presence is said to be pathognomonic of acute generalized miliary tuberculosis. We are not able to comment further on this important phenomenon, since few adequate ophthalmoscopic examinations were carried out.

Pulmonary findings consistent with the diagnosis of chronic pulmonary tuberculosis, usually apical in location, were reported in 36 cases. In 29 of them the disease was found at autopsy as diagnosed clinically. Of the 63 cases in the series, 18 were found at autopsy to show miliary involvement of the lungs in the absence of chronic pulmonary tuberculosis. No chest signs of any type were found on physical examination in 4 cases, diffuse fine to medium rales were found in 6, and various other nondiagnostic signs were encountered in the remaining 8 cases.

Enlargement of the *spleen* has been frequently reported in the literature as occurring in acute generalized miliary tuberculosis. Litten⁹ found a palpable spleen in 70 per cent of his cases. Hegler³ states that splenomegaly in the disease is frequent but that gross enlargement of the spleen is extremely rare. Amberson¹² holds that the spleen is palpable in a minority of cases. It is generally recognized that enlargement of the spleen at autopsy does not necessarily mean that the organ was palpable during life. In addition to the weight of the spleen, its palpability depends on other factors, including the experience of the examiner, the thickness of the abdominal wall and the degree to which the patient is able to co-operate. Obviously a spleen that is greatly enlarged by weight may not be palpable clinically if other factors are not favorable. We believe that a spleen weighing over 400 gm. should be palpable clinically, particularly if careful and repeated examinations are carried out. Under optimal conditions, spleens weighing considerably less may also be palpable. Abdominal palpation was reported in 49 cases. The spleen was described as palpable in 6 cases (12 per cent), and in 5 of these it was enlarged by weight (over 195 gm.) at autopsy. The largest spleen in the group weighed 1300 gm. and contained many tuberculomas in addition to miliary tubercles. Although 47 per cent of the spleens in this series weighed over 195 gm. at autopsy, only 4 (7 per cent) weighed over 400 gm., so that marked enlargement was rare both at physical examination and at autopsy.

Enlargement of the *liver* as a result of involvement in miliary tuberculosis is not usually described. Clinically, 35 per cent of these patients were reported to show palpable livers, but significant enlargement at autopsy was reported in only 6 per cent. In no case was it possible to demonstrate that hepatomegaly was due to miliary involvement of the liver per se.

Accumulation of serous fluids in amounts generally considered to be abnormally large was found at autopsy in many cases. Pleural fluid in amounts varying from 150 to 4900 cc. was found at autopsy in 19 cases (30 per cent) but was detected clinically in only 5 cases (8 per cent). Two cases in which no chronic tuberculosis of the lungs or pleura was found but in which diffuse pulmonary miliary tuberculosis was present showed significant amounts of fluid in the pleural spaces. Nine cases (14 per cent) showed abnormally large amounts of pericardial fluid at autopsy. In 5 of these, the amounts were relatively small, — from 50 to 75 cc., — and there were no symptoms during life attributable to the accumulation of fluid. In the other 4 cases, there was 150 to 800 cc. of pericardial fluid at autopsy. Two of these patients showed caseous tuberculous pericarditis before death. Miliary tubercles were found at autopsy in the pericardium in 2 cases, but in neither was there an abnormal increase in pericardial fluid. From 200 to 1500 cc. of intraperitoneal fluid was reported at autopsy in 4 cases (6 per cent), and the fluid was found clinically in 1 case.

Length of Hospital Stay and Duration of Disease

The shortest hospital course was twelve hours, and the longest was two hundred and twenty-five days. Seven patients died after being in the hospital for thirty-eight hours or less, and 6 remained there for three months or more. Most of the patients were in the hospital for two to four weeks. The length of the hospital stay and the duration of the disease are not, of course, necessarily synonymous. Most patients appeared to have developed the acute illness outside the hospital and to have sought hospitalization only when their symptoms became extremely severe. A few patients seem to have developed the condition while in hospital, and 1 patient suffered recurrent acute episodes, probably due to repeated miliary disseminations. In determining the apparent duration of the acute generalized miliary disease, such information was utilized as the onset of acute symptoms, the onset of febrile episodes, the changes in the leukocytes and x-ray information. Eighty-three per cent of the patients died two months or less after the apparent onset of acute symptoms, and the average duration of the illness was five and a half weeks. The shortest course in the series was five days in length, and the longest thirty-two weeks.

HEMATOLOGIC FINDINGS

Leukocytes

Adequate descriptions of leukocytic reactions in acute generalized miliary tuberculosis appear in the literature with some rarity. Warthin¹⁵ reported 2 cases in 1896 in which prolonged leukopenia and elevated percentages of neutrophils were found. As long ago as 1905, Arneith^{16, 17} pointed out that in this type of tuberculosis, as in the experimental

disease produced in animals by the intravenous injection of tubercle bacilli, it is the neutrophil that is most actively involved in the leukocytic reaction of the organism to the infection. He placed the emphasis on excessive demand for neutrophils rather than on defective supply in explaining the leukocytic changes. More recently, Medlar¹⁸ and Muller¹⁹ have expanded Arneth's views and have also directed attention to the important role of the neutrophil in tuberculous infection and to the demand made by local tuberculous lesions for such cells. The effects on the peripheral blood picture of such a demand seems to depend largely on the ability of the bone marrow to keep up with requirements. Thus, in any type of tuberculosis, if developing lesions make excessive demand for neutrophilic cells on the bone marrow, leukopenia may result. On the other hand, bone marrow response may be sufficient from time to time to produce frank leukocytosis. In either case many young neutrophils reach the circulating blood and the tendency for the count to shift to the left is more or less marked. That overwhelming infection, including tuberculosis, can at times produce what appears to be bone marrow depression is well known. There is no positive evidence, however, that the mere presence of miliary tubercles in the marrow can per se exert a depressant effect. In metastatic involvement of the marrow by neoplastic disease, Vaughan²⁰ found that the actual space occupied by neoplastic tissue was insufficient to account for the observed decrease in marrow function. Similarly, in none of our cases was there sufficient involvement of the bone marrow to allow explanation of peripheral blood changes on the basis of mechanical depression of marrow function. Interesting in this connection is the experimental work done by Doan and Sabin,²¹ who produced extensive lesions of the bone marrow in rabbits by intravenous injection of virulent tubercle bacilli. The result was initial depression of marrow function as judged by peripheral blood observations, followed in the animals that survived by compensatory hyperactivity of the marrow and finally by functional and morphologic recovery.

The increase in percentage of neutrophils and the more or less marked shift of the Arneth count to the left were stated by Arneth to be of definite prognostic and diagnostic value. Medlar¹⁸ considers, on the basis of numerous clinical observations, that in tuberculous patients an increase in the percentage and absolute number of neutrophils, whatever the total leukocyte count, is indicative of a progressive process. Such changes are not limited to acute generalized miliary tuberculosis but may be present in active pulmonary and other forms of active tuberculosis as well.

Our observations are based on 49 of the entire series of 63 cases. Eleven of the total number were excluded because of the presence of significant non-tuberculous infection at autopsy, 2 because no blood

counts were available, and 1 because of the presence of chronic myelogenous leukemia. So far as could be ascertained at autopsy, the 49 remaining cases showed no disease apart from the tuberculous infection that might have affected the blood picture.

Total leukocyte counts in the 49 cases were distributed as follows: in 24 cases (49 per cent) there was leukopenia (a total leukocyte count of less than 5000) at some point during the hospital course, in 14 cases (29 per cent) there was leukocytosis (a count of 10,000 or more) at some point during the hospital course, and in 16 cases (33 per cent) the total leukocyte counts were within the normal range. The highest total count was 20,700, and the lowest 1600.

In 11 of the 24 cases showing leukopenia at some time during the hospital course, the total leukocyte counts were persistently lower than normal for two weeks or more, the longest period of leukopenia being twenty weeks. In 6 cases, leukopenia, leukocytosis and normal total leukocyte counts were all observed. Seven patients showed leukopenia on entry but died before further observations could be made.

Differential leukocyte counts, like the total counts, varied in individual patients from time to time. A total of ninety differential counts was available in 35 of the 49 cases. Increased percentages of neutrophils, along with decreased percentages of lymphocytes, were observed in 31 cases (89 per cent). Immature neutrophils were extremely frequent, and in several cases the immature forms outnumbered the mature forms. In 4 cases there was an increased percentage of lymphocytes with a normal or slightly low percentage of neutrophils. Persistent monocytosis was not present in any case, although a slight increase in the percentage of monocytes was seen in thirteen of the ninety differential leukocyte counts available.

Of the 24 cases showing leukopenia, differential counts concomitant with low total leukocyte counts were available in 18. Fifteen of the 18 (83 per cent) showed an increase in neutrophilic elements, the highest percentage observed being 96. Immature neutrophils up to 25 per cent were observed in this group. Although 2 of the cases showing leukopenia also showed a slight decrease in neutrophilic elements, in none was there a picture consistent with or suggestive of granulocytopenia.

The combination of leukopenia and relative neutrophilia was striking. Although this combination, as indicated by Sturgis,²² is not limited to acute generalized miliary tuberculosis, it may be of diagnostic assistance. In typhoid fever, for example, the leukopenia is usually associated with relative lymphocytosis at the expense of neutrophils, and in true agranulocytic conditions the leukopenia is marked by extreme diminution of neutrophils and less marked diminution of lymphocytes.

Bone-marrow sections were made at autopsy in 37 of the 49 cases, and 33 of these contained miliary tubercles. The bone marrow in 19 of the 24 cases with leukopenia was involved by the miliary process and was uninvolved in 2 cases. No sections were available in the remaining 2 cases. In 9 of the 14 cases with leukocytosis, the marrow contained miliary tubercles, in 1 of the group no tubercles were present, and in 4 no sections were available. It is not surprising that no correlation between the hemopoietic activity of the marrow at the time of death and the blood picture during life could be es-

decrease in platelets and the resulting hemorrhagic diathesis. Armeth²⁷ reported extremely low platelet counts in 6 cases of this type of tuberculosis, all of which showed leukopenia and neutrophilia in addition. Two of our cases showed blood findings quite similar to those in Armeth's cases. The following points were common to both: moderate to severe leukopenia, with occasional normal or elevated total leukocyte counts, an increase in percentage of neutrophils, decreased platelets, normocytic or slightly microcytic anemia, and polychromatophilia. In addition, 1 case (Table 3) showed abnormal num-

established in the series. With regard to hemopoietic function, the bone marrow appeared normal or hyperactive in the overwhelming majority of cases, and definite hypofunction was noted in only 2 cases.

Hemoglobin and Red Cells

The occurrence of anemias of various types in pulmonary tuberculosis is discussed at length by Muller.¹⁹ Hegler³ gives the range of hemoglobin determinations and red-cell counts in acute generalized miliary tuberculosis as 65 to 85 per cent and 3,500,000 to 4,500,000, respectively. Both Hegler and Wintrobe²⁴ state that severe anemias in tuberculosis are rare.

In this series, 46 patients had both hemoglobin determinations and red-cell counts. Moderate normochromic anemia was seen in 39 (84 per cent). The lowest hemoglobin value and red-cell count were 43 per cent (Sahli) and 1,840,000, respectively. The vast majority of the determinations were well within the range given by Hegler.

Concomitant Depression of Blood Elements

The occurrence of a condition resembling so-called "aplastic anemia" in acute generalized miliary tuberculosis was noted by Dyke²⁵ and by Rosenthal,²⁶ the latter placing special emphasis on the

bers of nucleated red cells and increased numbers of immature neutrophils in the peripheral blood, findings consistent with the condition known as myelophthisic anemia and ordinarily associated with space-occupying lesions of the bone marrow. At autopsy the bone marrow contained relatively few miliary tubercles and showed markedly increased cellular density. There were signs of increased activity in both the erythrocytic and leukocytic series.

The second case of this general type in the early days of the hospital course showed a peripheral blood picture suggestive of an aplastic state. Blood studies done during this period all showed anemia, leukopenia and thrombocytopenia, and except for a slight to moderate increase in the percentage of polymorphonuclear cells, there was little peripheral evidence of compensatory activity on the part of the bone marrow. Subsequently there was steady improvement in the leukocyte picture, and when the patient died, four weeks after entry, a frank leukocytosis was in evidence. The appearance of the marrow at autopsy was in keeping with the findings in the peripheral blood in that there was increased granulopoiesis but decreased erythropoiesis. Miliary tubercles were present but were few in number.

PATHOLOGY

Pathogenesis

Since the original descriptions of acute generalized miliary tuberculosis by Bayle²³ and Laennec,²⁴ there has been considerable controversy concerning the pathogenesis of the disease. Much of this material has recently been reviewed by Auerbach.⁸

It has long been apparent that miliary disseminations are ultimately blood-borne. The condition is generally attributed to the release of relatively large numbers of tubercle bacilli, directly or indirectly, from a chronic focus, and it is about such foci that most of the controversy has centered. Laennec recognized a connection between a chronic tuberculous focus and miliary dissemination of the disease, a concept that was elaborated in some detail by Buhl¹⁰ in 1858. On the basis of autopsy findings, Weigert³¹ concluded that the disease stems from erosion and penetration of veins by extravascular tuberculous foci. Benda²² agreed in principle but suggested that tubercles of the venous intima, developing as a result of the lodging of a single bacillus or of several bacilli from the circulating blood, were ultimately responsible for the overwhelming release of organisms, resulting in acute generalized miliary tuberculosis. That a tuberculous lesion of the thoracic duct may initiate such a condition has also been postulated, and Hartwich¹⁰ states that such a lesion was apparently the origin of the miliary dissemination in 26 per cent of his cases. It appears from Auerbach's observations that chronic tuberculous foci, developing in lymphatic channels draining an infected area, ultimately break down and release tubercle bacilli into the venous circulation by way of the thoracic duct. This view is attractive from the anatomic standpoint, and it has in its favor the very extremely frequent involvement of lymph channels and lymph nodes draining chronic tuberculous foci.

Weigert's³³ tenet that chronic pulmonary tuberculosis renders the patient more or less immune to miliary disseminations can no longer be seriously considered. Auerbach's findings, as well as our own, are in complete disagreement with Weigert's statement on this point, since chronic pulmonary lesions were present in 64 per cent of his series and in 71 per cent of our own. Reisner³⁴ indicated the importance of chronic extrapulmonary foci, such as bone and genitourinary lesions, in the production of acute miliary disseminations, but in our series such foci were decidedly less frequent than pulmonary foci. Chronic pulmonary foci may give rise to chronic extrapulmonary foci, which in turn may originate acute miliary disseminations, and it is usually impossible to decide at autopsy which of the chronic foci was responsible for the acute episode.

A sudden release of large numbers of tubercle bacilli into the blood stream, whatever the site of origin, does not necessarily result in immediately

fatal disease. One of Auerbach's cases had four separate seedings of the lungs over a period of fifteen months, as demonstrated by x-ray and confirmed at autopsy. If, however, the number of organisms is large and the patient is unusually susceptible, the spectacular condition known as sepsis tuberculosa acutissima is said to occur. This condition is usually described as an extremely acute and generalized process that results in death before miliary tubercles have had time to form. At autopsy, small areas of necrosis containing numerous tubercle bacilli but provoking little or no cellular reaction are found scattered throughout the body. In addition to our 63 cases of acute generalized miliary tuberculosis, we noted 2 cases of chronic, healed miliary tuberculosis in which several disseminations had apparently occurred. No cases were found that could be classified as sepsis tuberculosa acutissima.

Criteria for Pathological Diagnosis

The establishment of suitable criteria for the pathological diagnosis of acute generalized miliary tuberculosis is far from easy. Our studies of the literature have failed to disclose any criteria that were entirely satisfactory. In practice, pathological diagnosis of cases in which the disease is truly overwhelming is not difficult. The difficulty arises when one attempts to decide just how generalized miliary involvement must be before a case may be labeled as acute generalized miliary tuberculosis. Clearly, the discovery of isolated miliary tubercles in a single organ does not justify the diagnosis, nor does the finding of numerous chronic but generalized lesions.

In selecting cases for a study of this type, one is unfortunately forced to establish definite criteria, even though dividing lines between various types of the disease are far from definite. We considered it essential to take the term "acute generalized miliary tuberculosis" literally so far as possible and made the following requirements for the pathological diagnosis: that the tubercles be acute, provoking little or no fibrous tissue reaction, that the disease be generalized sufficiently to involve the liver, spleen and at least one additional tissue, such as lung, bone marrow or kidney*, and that the tubercles conform, with regard to size, to the miliary description †.

Chronic Foci

The distribution of chronic tuberculous foci in this series is shown in Table 4. Chronic foci were found in 60 cases (95 per cent). The chronic lesions found in 45 of the cases (71 per cent) were all instances of fibrocaceous pulmonary tuberculosis. Intestinal lesions, present in 27 cases (43 per cent), were without exception chronic tuberculous ulcerations, and in 1 case the ulcerative process had pro-

*Three cases were included in which sections of liver or spleen were not available; numerous acute tubercles in four or more tissues other than these organs, however, were demonstrated.

†The size of the tubercles varies considerably, although most of those in our cases were 3 mm or less in diameter.

duced a spontaneous ileocolostomy. Distribution of the ulcerative lesions through the various portions of the intestine is shown in the table.

Chronic caseous lesions of lymph nodes were found in 37 cases (59 per cent). Infrequent examination of the thoracic duct probably accounted for the fact that this structure was found to be involved by chronic tuberculous lesions in only 4 cases.

Tuberculosis of the genitourinary tract, including the kidney, prostate, seminal vesicles, epididymis and testicles, occurred in 14 cases (22 per cent). Three cases in this group also showed tuberculous

meningitis, a finding apparently not in keeping with the frequent relation between tuberculous meningitis and tuberculosis of the genitourinary tract described by some authors.^{6, 7}

Chronic lesions of the cardiovascular system were seen in 5 cases. In 1 case, a caseous lesion of the tip of the right auricular appendage, measuring 0.9 by 0.5 cm., was found to have ulcerated through to the endocardial surface, at which point there was a small mural thrombus. Chronic lesions were found in the pulmonary vascular system in 3 cases—in the pulmonary artery in 2 and in a small branch of the pulmonary vein in 1. One of the lesions of the pulmonary artery took the form of a verrucous arteritis, and a fungating gray mass, approximately 0.7 cm. in diameter, was found attached to the intima 1 cm. above the pulmonary valve. Microscopically, the lesion contained numerous tubercle bacilli and cellular debris enmeshed in a fibrin network. Finally, there was 1 case of intimal tuberculosis of the ovarian vein.

Miliary Distribution

According to Auerbach,⁸ in cases in which miliary seeding is extensive, routine microscopic examination discloses miliary tubercles in almost all parenchymatous organs. Obviously, the number of organs routinely sectioned influences in large measure the apparent distribution of miliary lesions. Since the number of organs routinely examined varies considerably from laboratory to laboratory, many of the reported differences in miliary distribution are fictional.

Litten⁹ and most modern writers^{5, 8} state that the lungs, liver, spleen, kidney, bone marrow and choroid are always involved in acute generalized miliary tuberculosis and that the voluntary muscles are always spared. Miliary tubercles of the skin have been reported, but this finding appears to be extremely rare.³⁵

The miliary distribution in this series is presented in Table 5. The almost invariable involvement of

the liver and spleen is well known. Our figures for these organs (100 per cent) may be artificially high, since the cases were selected on the basis of the finding of miliary tubercles in these sites. The extremely frequent involvement of the bone marrow has likewise often been pointed out. In the present series the bone marrow contained miliary tubercles in 84 per cent of the cases. Renal involvement by the miliary process occurred in 51 per cent, and the adrenal glands were diseased in 42 per cent. The latter figure is considerably higher than that found by Lewison et al.⁵ Although sections of the pancreas were made in only 25 cases, it is noteworthy that miliary involvement was found in 5 cases, a rather high incidence according to previous reports. Meningeal involvement was lower than is generally re-

ported, reasons for this discrepancy have already been mentioned. Miliary tubercles have often been noted in the thyroid gland, but in none of these cases was the gland examined. For the same reason, the frequency of involvement of the ocular choroid could not be determined.

DISCUSSION

From a practical point of view, more accurate diagnosis of acute generalized miliary tuberculosis is desirable for two reasons: first, the prognosis in the disease is considerably worse than that in most other forms of tuberculosis and may influence the physician's management of the case; second, more careful and detailed observations before death, particularly in the laboratory, may yield information of general value in tuberculosis.

The history often supplies no information of value, but may disclose either previous significant exposure to tuberculosis or the existence of chronic tuberculous infection. The incidence of acute generalized miliary tuberculosis among adults, particularly among those suffering from fibrocaceous pulmonary tuberculosis, was higher in this series than has generally been reported.

The course of the temperature is usually extremely irregular and is of little or no help in arriving at the correct diagnosis. More or less marked, sustained elevations of the respiratory and pulse rates may usually be expected. Although classification of cases of the disease into pulmonary and typhoidal types on the basis of temperature, pulse and respiratory charts figures prominently in the older literature, we doubt the justification for or clinical importance of such classification.

On physical examination, actual observation of miliary tubercles is possible only by ophthalmoscopic examination. We believe that a considerable number of our cases would have been correctly diagnosed before death had careful and repeated ophthalmoscopic examinations been carried out. Pulmonary findings in this series either were those of chronic pulmonary tuberculosis or were equivocal. Splenomegaly on physical examination occurred so infrequently that it was of relatively little diagnostic assistance. Spleen weights at autopsy sustained the finding at physical examination that pronounced splenomegaly in the disease is infrequent.

Among laboratory procedures the diagnostic importance of x-ray examination of the chest is fully established and needs no further comment. The importance of biopsy of the bone marrow as a laboratory procedure in the diagnosis of the condition was evidently not fully appreciated by the physicians in charge of our cases. Schleicher³⁶ has recently laid proper emphasis on this point and has described a method by means of which tubercles may be visualized in material obtained by marrow aspiration instead of biopsy. In view of the frequent involvement of the marrow at autopsy, it is apparent that

a definite ante-mortem diagnosis may be reached by ante-mortem examination of the marrow, a procedure that should certainly be resorted to in suspicious cases.

Serial examinations of the red and white cells appear to be of considerable diagnostic assistance, but isolated examinations are probably misleading as often as they are helpful. The most constant change in the leukocytic picture seems to be an increase in the percentage of neutrophils and a shift of the Arnett count to the left. These changes may be present whatever the total leukocyte count, but their diagnostic value is enhanced if they are found in association with leukopenia. None of these changes are specific for acute generalized miliary tuberculosis. When they are seen in patients known to be suffering from a chronic form of tuberculosis, the condition should be considered. If such a disturbance of the leukocytic picture develops in cases of obscure, febrile illness in which no specific bacterial agent is demonstrable, the disease should rank well up among the diagnostic possibilities.

Peripheral depression of several blood elements concomitantly, including leukocytes, red cells and platelets, is consistent with the diagnosis of acute generalized miliary tuberculosis but was not frequent in this series.

The chronic focus from which acute generalized miliary tuberculosis originates in a given case can seldom be definitely identified, but in the light of recent reports and of our own findings, we believe the lymphovenous route to be the likeliest one in the majority of cases, if not all. Chronic tuberculous lesions often develop in lymph nodes and channels draining an infected area. From this point, tubercle bacilli may easily enter the venous blood by subsidiary lymph channels and the thoracic duct. The latter structure may itself become incidentally infected, and less frequently it is involved from without by adjacent chronic lesions.

Many questions with regard to the distribution of miliary tubercles in acute generalized miliary tuberculosis remain unanswered. The frequent involvement of such sites as the liver, spleen, lungs and bone marrow is well established, but knowledge of the frequency of involvement of certain other sites is incomplete. Routine microscopic examination at autopsy of the ocular choroid, thyroid and pituitary glands, pancreas and adrenal glands in suspected cases would doubtless provide many of the answers not yet available. Our findings suggest that the adrenal glands and pancreas may be somewhat more frequently involved by the miliary process than is usually reported.

CONCLUSIONS

The general incidence of acute generalized miliary tuberculosis at autopsy among adults at the Boston City Hospital from 1937 to 1941, inclusive, was 1.55 per cent. The incidence of the condition among cases

of tuberculosis of all types at autopsy for the same period was 20.3 per cent

Although chronic pulmonary tuberculosis was diagnosed fairly accurately in this series, the clinical diagnosis of acute generalized miliary tuberculosis was achieved in only 25 per cent of the cases. The history and physical findings were of limited diagnostic assistance, x-ray examination of the chest and the clinical course being much more important in this respect. The only direct means of visualizing the miliary tubercles during life—namely, by ophthalmoscopic examination and bone-marrow biopsy—were grossly neglected in this series.

Splenomegaly was observed on physical examination in 6 cases (12 per cent), and the finding was confirmed at autopsy in 5. The spleen weighed over 195 grams at autopsy in 47 per cent of the cases, but enlargement by weight was marked (over 400 gm) in only 7 per cent. The average duration of life after apparent onset of the disease was five and a half weeks, the shortest course being five days and the longest thirty-two weeks.

Increased percentage of neutrophils and shift of the Arneth count to the left were present in 89 per cent of the 35 cases in which differential counts were made. Leukopenia was frequently seen but was by no means the rule.

Chronic tuberculous lesions were found in 95 per cent of the series. The lung was the site most frequently involved, being affected in 71 per cent.

The organs most frequently involved by miliary lesions were the spleen, liver, bone marrow, lungs, kidneys and adrenal glands. Some of the difficulties in establishing the frequency with which a given organ is involved by the miliary process are discussed.

THE LATE RESULTS OF FEMORAL THROMBOPHLEBITIS AND THEIR TREATMENT*

JOHN HOMANS, MD†

BOSTON

THE GROUPS OF LATE RESULTS

THERE is probably an advantage, in these recent days when thrombosis in the veins of the lower limbs is receiving active treatment by surgical procedures as well as by anticoagulants, in visualizing the usual end stage of the disease untouched by such methods. It is as yet too soon to learn how much or how little they alter its natural course, even supposing that in any considerable proportion of cases their use is attempted, for when one considers that venous thromboses occur in association with injuries, operations, childbirth and serious cardiac and other diseases, as well as spontaneously in everyday life, it is probable that in most instances today, the disease still has an opportunity to reach its full development.

In the light of present-day researches, culminating in the clinical observation of Bauer¹ and the pathological studies of Hunter and his associates,^{2, 3} it is clear that most venous thromboses begin below the knees. Undoubtedly they are then able to pursue a variety of courses, the nature of which has often been pointed out.‡ But how many undergo spontaneous cure, how many retain their character of soft thrombi likely to cause pulmonary embolism, and how many develop into the familiar, obstructive femorotibial thrombophlebitis is unknown. Certainly an obstructive, inflammatory thrombosis is the late stage toward which all such processes tend, and it is highly probable that it is by far the most frequent end result of all venous thrombosis in the lower limbs. I shall resist the temptation to show how surgical interruption of the diseased vein or the use of anticoagulants may modify or even prevent this development, and how, in the early stage of an actual thrombophlebitis, lumbar sympathetic block may favorably influence peripheral vasoconstriction and edema. These matters, of course, should sometime be studied in the light of the findings secured by such investigations as the present.

The late results of femorotibial thrombophlebitis seem to be divisible into five groups, and although some cases present features characteristic of more than one group, most of the 156 that form the basis of this report are easily classified. I have made no attempt to include the many patients I have seen in hospital wards, for these represent almost exclusively the disabling state of ulceration characteristic of Group 2. If included, they would still further enlarge that group.

Group 1 Some degree of edema remains, so that the ankle and lower leg swell during the hours of work or standing, discomfort is unimportant, congestion is not a feature, the skin is healthy, and the edema recedes, or even disappears, overnight. This group is large — how large is difficult to say, since many patients who fall into it make no complaints. I have included my own few cases, both for statistical purposes and for my brief account of treatment, with Group 2, for it is splitting hairs to isolate the mild edemas with negligible cutaneous changes from the serious ones complicated by pigmentation, induration and ulceration.

Since edema is the basic disorder in both groups, this is perhaps the best place to explain that it is likely to be due, not only during but after the acute stage of thrombophlebitis, to several causes — namely, elevated venous pressure, peripheral vasospasm (in the arterioles and venules) and impaired lymphatic drainage. These causes are so often combined that only occasionally is it possible to say that one of them alone predominates.

Group 2 Postphlebotic pigmentation and induration are present, and ulceration, in a variety of forms, often occurs. This group is far larger than any other. I find 95 cases, or 61 per cent, that fall into Groups 1 and 2. Edema is a constant feature. The typical lesion is usually referred to as "varicose ulcer," although varicose veins are seldom associated with it and, even if present, have no causal relation to it.

The characteristic physical signs are cutaneous pigmentation, diffuse induration, local heat and often ulceration, in the lower two thirds of the lower leg, usually on its inner face above the ankle. Sometimes this disorder is most marked near and below the malleoli, the inner rather than the outer. "Varicose eczema" is occasionally seen. There is thought to be present, according to Thompson's⁶ interpretation, a vicious circle of edema and sensitization of the tissues to foreign protein absorbed from the feet, toes and nail beds. The antigen is probably retained in the edema fluid for long periods.

*Presented at the postponed 1945 annual meeting of the New England Surgical Society, Boston, February 6, 1946.

†Surgeon emeritus, Peter Bent Brigham Hospital.

‡It is difficult to see why a soft and, at first, nonobstructive thrombosis should, in time, if it does not cause either fatal embolism or end in healing by local organization, go over to the obstructive, inflammatory type of disease. But Bauer has followed the process through, by phlebography, and one certainly encounters its earlier stages as betrayed by nonfatal embolism or local soreness, lameness (with or without swelling) and muscular irritability before the typical phlegmasia alba dolens sets in. Moreover, the pathological studies of Hunter, Sneed, Robertson and Snyder and of Hunter, Krygier, Kennedy and Sneed are consistent with earlier German and Swedish investigations in showing how frequently lower leg venous thromboses can be found in persons dying after confinement to bed by a great variety of diseases. One is thus made to realize that such thrombosis is common as a terminal affair and that it could readily go on to more advanced stages if death did not supervene. Again, Conner's⁴ account of prodromal signs in the legs and feet in the typhoidal thrombophlebitis of earlier days is strong evidence for early local lower leg thrombosis as leading to the full blown thrombophlebitis. I have attempted in a recent publication⁵ to picture diagrammatically the various courses that lower leg venous thrombosis may pursue.

of time. Actually, it appears to injure the walls of the arterioles, causing extravasation of blood, — hence the pigmentation, — and gives rise to a slow necrosis of fat with scar formation. Ulceration is not a primary feature. The source of the supposed antigen may be a fungus, — *Trichophyton*, — although in some cases it seems to be bacterial. In occasional cases, varicosity of the saphenous system, secondary to the original thrombophlebitis, contributes to the local disorder.

Group 3. A pain complex becomes established early in the convalescence and irrespective of all other signs. The situation and distribution of the pain have no relation to any of the great nerves. With it are usually associated vasomotor changes in the skin of the affected leg and a stocking-like paresthesia, the whole giving the impression of a functional disorder. This is a fair-sized group, there being 27 cases, or 17 per cent.

Group 4. The leg is the seat of marked venous congestion. The foot and ankle are usually involved, being slightly cyanotic with prominent surface veins. There may be distended veins on the abdominal wall and in the groin. Edema is not necessarily present, nor postphlebotic induration and pigmentation. This is the smallest group — 8 cases, or 5 per cent.

Group 5. Recurrent thrombosis occurs in the deep and, often, the superficial veins. This takes the form of attacks at varying intervals over a period of years. The attacks, because they usually involve veins previously thrombosed and canalized, are less outspoken than the original thrombophlebitis. They are an occasional source of recurrent, and therefore nonfatal, pulmonary embolism. This is a moderate-sized group of 26 cases, or 17 per cent.

TREATMENT

Although treatment is not of primary concern here, some account of what appear to be appropriate methods of managing the various groups is in order.

Groups 1 and 2. Since edema is the basic difficulty, it is obvious that its relief will cure early, mild cases and will favorably influence late, advanced cases, even though cutaneous and subcutaneous changes are well established.

The relief of postphlebotic edema is best initiated by a few days in bed, with the foot of the bed elevated 4 to 6 inches. Free exercise of the legs, to forward lymphatic drainage, is encouraged. This is a desirable introduction to any specific treatment.

If even a short, continuous stay in bed is impossible, at least the patient can sleep in a bed so elevated and can supplement such gravity drainage during the day by a number of ten-minute periods during which the leg is raised on an inclined plane to an angle of 20 to 30° and gently exercised. When going about or working, the patient should wear a semielastic bandage or elastic stocking from toes to knee, stand as little as possible and avoid sitting with the legs dependent and relaxed.

Hand in hand with the relief of edema goes treatment of the skin, intended to do away with sources of absorbed protein substances, chiefly derived from fungi. The nails must be softened by soaks, accumulations beneath them being gently scraped away. Partly depending on the acuteness or chronicity of such infections, soaks, liquid applications, ointments and powders may be used, a matter calling for expert dermatologic knowledge and technic. It is probably important that local applications should alter the reaction of the skin, in which direction it is not easy to say, but it is perhaps best in the direction of increased acidity.

Actual ulceration brings up the problem of secondary infection, possibly by anaerobic or facultative anaerobic bacteria, and calls for bacteriologic studies and the internal as well as the external administration of appropriate drugs. Only the ulcer not chronically infected will be cured by relief of edema and venous stasis alone. Should varicose veins be present, section or, rarely, excision should be used to relieve back pressure. Sclerosing injections seem always to do harm, in that they increase the local inflammatory reaction. Radical resection and skin-grafting of the diseased tissues should only occasionally be used.

Group 3. This group is characterized, as I have pointed out in an earlier publication,⁷ by a pain complex, and is distinguishable only by a history of thrombophlebitis from the "minor causalgia" that occasionally follows injury. It is, however, rather more responsive to treatment, and its identification is not difficult. The pain is "bursting" or "throbbing" or radiates down the center of the leg, being brought on, equally often, by exercise or long standing. The leg usually appears a little enlarged and, as a whole, faintly cyanotic, although dilated veins are absent. Below the knee, the skin is slightly "numb," — that is, dull to pinprick, — but distribution of the numbness does not follow the fields of the sensory nerves. Squeezing the calf as by a blood-pressure cuff, is very disagreeable. The peripheral pulses in the foot are sometimes diminished, — one of them may even be absent, — suggesting some degree of constriction of the large arteries.

Probably this state is residual from the vasomotor disorder of the acute stage of thrombophlebitis, for it is almost invariably relieved, for the moment at least, by sympathetic lumbar block. Successive reinforcing blocks prolong the period of relief and usually effect a cure. In late and obstinate cases, sympathectomy is required.

Group 4. This group, comprising the cases presenting venous congestion, yet with little or no edema, is one from which surgery has in the past been held to be barred, apparently on the ground that all distended veins, visible or invisible, are still capable of carrying blood uphill and must not be disturbed. This attitude should decidedly be recon-

sidered, no valveless veins draining the lower limbs—except the iliac veins and vena cava—are capable of forwarding blood against gravity, and since the column of blood they contain transmits high back pressures on lifting, straining and coughing, their interruption must always benefit and can never harm the venous return. Moreover, the blood that accumulates in, and even flows down, these veins must be carried by collateral vessels, which do the

back pressure. The canalization of thrombosed vessels is well known to pathologists, a process that I have illustrated in the accompanying diagrammatic sketches (Fig 1). The conditions pictured have actually been noted at operation. It would have been better if the veins had remained plugged, as Bauer,⁸ on phlebographic grounds, holds to be the rule.*

With these matters in mind, the femoral and saphenous systems of the congested postphlebotic

FIGURE 1 Semidiagrammatic Scheme of a Bilateral Obstructive Thrombophlebitis in the Lower Limbs

The process extends higher on the left than on the right. A represents the acute stage before organization, 1 and 1 being cross sections of the thrombosed femoral veins. B represents a later stage. In the right leg the thrombus has become a solid fibrous mass, shown in cross sections 2 and 3. In the left leg, the thrombus has been divided by multiple channels, shown in cross section 4. Both these conditions have been encountered on exploration.

work of the functionless veins. Presumably, the great veins sometimes seen in the groin and upon the abdomen of those who have suffered a long-continued plugging of the femoral and iliac veins are, in the acute stage of obstruction, the principal means of transmitting the venous return from the legs. Later, as alternative routes, by means of valved veins within the muscular envelope, are opened up, these overdilated veins become functionally useless. One can easily demonstrate the downflow of blood in all such vessels by the tests applicable to varicose veins in general.

The once thrombosed femoral vein itself must also be presumed to be a direct source of congestion and

leg may be studied and, if necessary, explored by a liberal incision in the groin. The saphenous vein should first be exposed and, if found diseased, divided at its point of entry into the common femoral. The femoral vein should then be inspected from this point downward for several centimeters—well below the entrance of the profunda femoris. It will usually be surrounded by scar tissue and will be

*Bauer's study of the sequelae of thrombosis takes up most thoroughly, many aspects of the problem but gives no descriptions of the actual state of the once thrombosed veins, as seen on section at the operating table or at autopsy. Moreover his phlebographic evidence that the veins superficial to the muscular envelope constitute the principal collateral pathways, ignoring the great intermuscular plexuses and their deep connections with the pelvis, is decidedly open to adverse criticism. Perhaps the superficial veins do offer the easiest way out for the venous blood when the patient lies flat as during phlebography but this does not mean that deeper vessels are not used in the erect position and during exercise.

of time. Actually, it appears to injure the walls of the arterioles, causing extravasation of blood, — hence the pigmentation, — and gives rise to a slow necrosis of fat with scar formation. Ulceration is not a primary feature. The source of the supposed antigen may be a fungus, — *Trichophyton*, — although in some cases it seems to be bacterial. In occasional cases, varicosity of the saphenous system, secondary to the original thrombophlebitis, contributes to the local disorder.

Group 3. A pain complex becomes established early in the convalescence and irrespective of all other signs. The situation and distribution of the pain have no relation to any of the great nerves. Probably this state is residual from the vasomotor disorder of the acute stage of thrombophlebitis, for it is almost invariably relieved, for the moment at least, by sympathetic lumbar block. Successive reinforcing blocks prolong the period of relief and usually effect a cure. In late and obstinate cases, sympathectomy is required.

Group 4. This group, comprising the cases presenting venous congestion, yet with little or no edema, is one from which surgery has in the past been held to be barred, apparently on the ground that all distended veins, visible or invisible, are still capable of carrying blood uphill and must not be disturbed. This attitude should decidedly be recon-

am going to go farther than Dr Homans and tell you what my experience has been in treating these cases. Long ago I was disturbed by seeing so many cases of obviously deep thrombophlebitis, characterized by thrombophlebitic ulcers without varicose veins, and with a history of repeated high saphenous divisions, without any obvious improvement in the ulceration.

As long ago as twenty-five years, Dr Homans suggested that the flap operation in the lower leg, with division of the perforating veins, might well be the answer. Dr Linton, I think, revived this idea, and suggested that these flap operations be more extensive, that they be done also in the lateral aspect of the leg, and that the appropriate perforating veins be divided. This does not seem to me to be sufficient. In addition, Dr Collier has suggested femoral divisions. This is not the answer.

Most of these cases, as Dr Homans has suggested, are associated, with reflex arterial spasm, which manifests itself by increased sensitivity to cold, increased sudomotor activity and the typical brawny edema and stiffness of the extremities, sometimes with atrophy of bone. I have come to believe that, after these patients have been subjected to procaine block, if they seem to improve, they should be immediately subjected to sympathectomy.

There is no doubt in my mind that patients who have had chronic thrombophlebitis have a tendency to develop recurrent thrombosis. If this is so, there is a grave danger of their developing a propagating thrombus and a lethal embolus. Heretofore my routine procedure has been to do a primary division of the superficial femoral vein, followed by lumbar sympathectomy. I have found that this is not enough, and have dissected the lower leg as well, doing a flap operation. Only by this method, I am sure, can one begin to salvage some of these unfortunate cases.

This seems like a great deal of surgery, but, as Dr Homans has mentioned, it makes little difference how much one divides these deep vessels so long as one does so high enough and

performs the subsequent operative procedures that clear up the lesions.

Concerning injections in postphlebotic legs, I mention them only to condemn them, because they are of no value and should not be done. This procedure is in the same category as dividing saphenous veins for deep thrombophlebitis.

Dr HOMANS (closing) I should like to say a word more about the pain complex, which fascinates me. Actually one does see it without other signs, in a leg that may look almost normal or show only a little bit of edema. Yet the patient makes a bitter complaint on having to stand a good deal and on taking exercise.

The most obvious things that one finds in going over a patient suffering from a pain complex are the peculiar, stocking-like paresthesia, which makes one think it is a hysterical affair, and the tenderness or soreness felt on compressing on the calf. These are the signs that mark this condition and the signs that are relieved, along with the pain, by blocking the sympathetic system. I have not paid so much attention as I ought to, perhaps, to the pain problem in the presence of other postphlebotic difficulties.

There is one matter that should not be slighted in treating these postphlebotic states, and that is the varicose veins that actually may develop, probably because of the dilatation that takes place while the main venous pathway is obstructed. One has to deal with these as one would deal with any varicose veins. It is well to have this in mind, but do not operate on a saphenous vein thinking you are going to cure the postphlebotic lesion. You may help it a little when the vein is obviously varicose, but the old idea of excising great areas of scarred and ulcerated tissue I have given up, probably because of increasing years. It is hard work and one does not get so much result from one's effort as one would like. Instead, a great deal can be accomplished by lessening the edema and treating the skin in the postphlebotic states, and thereby one is spared, and the patient is also, the labor and difficulty of some of these elaborate procedures.

DEXTROCARDIA AND BRONCHIECTASIS

A Review of the Literature and a Report of Two Cases

A. H. RUSSAKOFF, M.D.,* AND HARVEY W. KATZ, M.D.†

BIRMINGHAM, ALABAMA AND NEW HAVEN, CONNECTICUT

IN THIS decade of increasing mass radiography, when the United States Public Health Service, state health departments, tuberculosis associations, private industries and other agencies are interesting themselves in x-ray survey programs, it is not amiss to call attention repeatedly to nontuberculous diseases of the chest. In most cases during the conduct of chest x-ray surveys, persons who are found to have such abnormalities are referred to their private physicians — not to specialists — for further investigation. Consequently, it is incumbent on progressive physicians to become well versed in the roentgenographic as well as the other aspects of diseases of the chest. Although no disease of the chest constitutes a public-health problem of the magnitude of pulmonary tuberculosis, others are of paramount importance to the health, welfare and livelihood of those persons concerned.

The purposes of this paper are to report 2 cases of dextrocardia and bronchiectasis, to call attention to

this clinical entity among nontuberculous diseases of the chest, which will be recognized more frequently during the ensuing years and to present evidence that transposition of the viscera is attended by a high incidence of other significant abnormalities.

The coincidence of bronchiectasis and dextrocardia was first reported by Siewert¹ in 1904. From that time until 1933, only 2 additional cases appeared in the literature.²⁻³ At that time, in recording 4 cases, Kartagener⁴ observed the coincidence of sinus disease in association with bronchiectasis and visceral transposition. The simultaneous occurrence of these three conditions has been termed "Kartagener's triad." Kartagener, who was a proponent of the theory of the congenital origin of bronchiectasis, maintained that these cases lent proof to this tenet. In 1935, Kartagener and Horlacher⁵ reported 7 additional cases, which were found in several European clinics.

Two years later, Adams and Churchill⁷ published the first paper in the English language on this subject. Among 23 cases of situs inversus, they found 5 with bronchiectasis. A review of embryologic data

*Assistant professor of preventive medicine, Alabama Medical College, formerly director, Division of Tuberculosis Control, State of Alabama, Department of Public Health.

†Clinical instructor of medicine, Yale University School of Medicine.

whitish, instead of its usual blue color. Often the heavy scar of the organized thrombus can be felt, the vein being a solid-feeling cord, which, however, is actually distensible. In the figure, the state of the femoral and iliac veins, as I have seen them on section at the operating table, is diagrammatically pictured. Whether I am right in believing that the canalizing process is as complete as I have suggested may, of course, be questioned. In any case, the vein that I have described is functionally useless and can be divided with impunity.

Far from aggravating the signs of venous stasis, a common femoral or iliac division results in lessened distention of the superficial veins and an improved color of the foot. Any edema that is present may be diminished, although edema and its complications are less likely than venous congestion to be relieved, as Collier and his associates^{9, 10} have reported in studying the results of femoral-vein interruption. Their indications are mainly chronic induration and ulceration, rather than the venous stasis that I have described here, and the recurrent thrombosis described under Group 5.

If distended veins on the pubis and abdominal wall are proved to be functionless, they may be reduced in number and size by section and perhaps injection, but although my experience indicates that their obliteration does no harm, it has also shown that it is even more difficult to make permanent than is the case with varicosities of the legs.

Group 5. Cases of recurrent thrombosis, with or without embolism, naturally present no consistently abnormal appearances. The affected leg usually shows some of the aftereffects of the original thrombophlebitis. Pulmonary infarcts rarely recur without other evidence of old or fresh thrombosis, in which event it must be supposed that a thrombus forming in a canalized, useless vein is locally silent. I have a record of one such case, in which repeated pulmonary infarction simulated angina pectoris and the patient had been made an invalid.¹¹ Section of the external iliac vein prevented further recurrence. On division of the vein, ribbonlike masses of scar tissue were noted, much like those shown in the figure.

In other cases, there has been a history of recurrent swelling and lameness of the calf. In yet others, small superficial local thromboses have pointed very strongly to the presence of a deeper process, of which they are merely a complication.

Although section of the common femoral vein must often serve, the ideal treatment for all such recurrent thromboses is ligation of the corresponding common iliac vein, because this high division secures the best collateral venous circulation and gives the greatest help in the prevention of future thrombosis and embolism. Unfortunately, a previously, and perhaps repeatedly, thrombosed common iliac vein is difficult and sometimes dangerous to deal with, for it is frequently found to be both adherent and

fragile, requiring the greatest care in handling. Ligation of the vena cava may even be required.

SUMMARY

On the reasonable presumption that femoriliac thrombophlebitis is the usual end stage of thrombosis in the deep veins of the leg, an attempt has been made to group the various abnormal states that follow such a thrombophlebitis. Five groups of patients have become distinguishable among the ambulatory persons who present themselves as office patients—namely, those characterized, respectively, by edema, by edema plus induration, pigmentation and ulceration, by a pain complex, by venous congestion and by recurrent thrombosis.

These groups overlap, yet by a study of the clinical history and physical signs, every patient can be placed, for purposes of treatment, in one group or another.

Appropriate means of treating the members of each group are suggested.

It will be a matter of great interest to discover how modern treatment, especially of the earlier stages of venous thrombosis in the lower limbs,—that is, by operation and anticoagulants,—influences the establishment of femoriliac thrombophlebitis and its late results.

DISCUSSION

DR. E. EVERETT O'NEIL (Boston): This is a new grouping of cases that Dr. Homans has outlined, and for anyone who sees a large number of these conditions, it is an excellent working formula. The second group that he mentioned, which manifests itself by a tremendous amount of induration and ulceration and scarring in the lower inner third of the leg, represents what is probably one of the most difficult venous conditions with which the surgeon has to deal. This problem has engaged my interest for several years.

The third group mentioned, in which pain alone is an outstanding phenomenon, has not in my experience been observed alone. It is usually found, so far as I am concerned, in conjunction with the other phenomena of ulceration, induration and scarring.

So far as the treatment of the second group is concerned,—and to me this is the most important of the five groups,—I

found that 1.13 per cent of 442,252 persons examined in surveys showed some type of significant nontuberculous aberration. Of the entire group, 0.6 per cent had abnormal hearts, whereas 0.009 per cent (approximately 1 in 11,000 persons examined) had dextrocardia. Scatchard and Duszynski²⁴ reported 1 case of dextrocardia in 2721 roentgenographic examinations in a general hospital. Morse²⁵ found 36 cases among 223,182 examinations, a frequency of 1 in 6200. Russakoff²⁶ has observed 6 cases among 36,717 persons examined in surveys, a frequency of 1 in 6120.

Olsen⁸ in reviewing the files of the Mayo Clinic from 1920 through 1941 found 85 cases of dextrocardia. Of these, 14 were discovered to have an associated bronchiectasis, an incidence of 16 per cent. During this identical period a diagnosis of bronchiectasis was made on less than 0.5 per cent of all other patients investigated. Thus, the frequency of bronchiectasis in this series was thirty-three times as great among persons with dextrocardia as among a representative clinic population. Kartagener and Horlacher⁵ found 23 per cent of their patients with dextrocardia to have bronchiectasis, and Adams and Churchill⁷ found this correlation to exist in 22 per cent of their group. It is interesting to note that Morse²⁵ reported 1 case of bronchiectasis in his group. His study, however, deals only secondarily with cases of dextrocardia, and it is therefore assumed that a complete study for bronchiectasis in all cases was not made.

Although it may justifiably be argued that the true incidence of bronchiectasis in a representative clinic population is probably in excess of 0.5 per cent, it is still undeniable that the coincidence of bronchiectasis with visceral transposition is unusually high. Thus, the obvious conclusion to be drawn from these studies is that the consistently high incidence of bronchiectasis among patients with dextrocardia is hardly to be explained as a chance occurrence.

Dextrocardia is altogether too frequently considered to be an anomaly of little if any significance, yet Olsen⁸ observed that 11 of his patients, exclusive of those with bronchiectasis, had additional significant defects and 2 others had cardiospasm. Thus, of 85 persons with dextrocardia, 32 per cent had other significant abnormalities.

* * *

These observations obligate physicians to adopt a somewhat different attitude toward cases of dextro-

cardia. It is no longer sufficient to inform the patient of transposition of the abdominal viscera in cases of situs inversus to avert the catastrophes of improperly interpreted contralateral abdominal manifestations. Besides a search for other anomalies, a thorough investigation of the upper respiratory system and the bronchopulmonary tree should be an integral part of a complete clinical study. Bronchography should perhaps be performed with less conservatism in such cases than is practiced among patients without dextrocardia.

With recognition of the fact that more cases of dextrocardia are bound to be uncovered in practically every community as a byproduct of mass radiography in the control of tuberculosis, it is timely that physicians take cognizance of the high incidence of significant abnormalities associated with this condition.

led them to conclude that the bronchiectasis in these cases represented a stigma of maldevelopment. In 1943, Olsen⁸ reported 14 cases of bronchiectasis among 85 patients with dextrocardia. This is the largest single group of cases reported to date.

Besides the reports already mentioned, the following are noted: Nüssel and Helbach's⁹ 2 cases and single case reports by Behrmann,¹⁰ Casaubon and Derqui,¹¹ Wernli-Haessig,¹² Glaum,¹³ Becker,¹⁴ Rosenthal,¹⁵ Ingraham,¹⁶ Cole and Nalls,¹⁷ Nagy,¹⁸ Adland and Einstein,¹⁹ Meyer,²⁰ Richards²¹ and Delp.²² Including the 2 cases that follow, there are 50 cases of dextrocardia and bronchiectasis on record.

CASE REPORTS

CASE 1* L M O, a 34-year-old man, was admitted to the Bryce Hospital, Tuscaloosa, Alabama, in 1934 with a diagnosis of mental deficiency and psychosis. In the past he had been subject to frequent respiratory infections and severe sore throat. The family history was noncontributory. On examination the patient was found to be dull and childish. He coughed frequently, producing foul, yellow, tenacious sputum. The significant findings were as follows: a deviated septum with both nares occluded by a mucopurulent discharge, dental caries and fetor oris, diffuse injection of the pharyngeal mucous membrane with copious postnasal drip, palpably enlarged lymph nodes in the anterior

FIGURE 1 Case 1

cervical chain, dextrocardia with no enlargement, arrhythmia or auscultatory abnormality, an admixture of dry and moist rales over both lower lung fields, and evidence of transposition of the abdominal viscera.

Additional studies included a conventional radiogram of the chest, which demonstrated the dextrocardia. The bronchial markings into both lower lung fields were decidedly

exaggerated, and there was evidence of peribronchovascular inflammatory change. Bronchography of the right lower lobe (Fig 1) showed a cylindrical type of bronchiectasis. A plain film of the sinuses demonstrated a bilateral chronic frontal and maxillary sinusitis.

CASE 2 P S, a 7-year-old girl, is the private patient of one of us (H W K). The prenatal history and delivery were uneventful. Within 24 hours after birth the infant had cough and cyanosis. X-ray examination of the chest at that time revealed dextrocardia, without parenchymal change. There was subsidence of the cough and cyanosis within a few days. The patient had had a chronic cough productive of a mucoid expectoration since early life. When 4 years of age, she received tonsillectomy and adenoidectomy. Following this procedure, it is believed that the cough became less productive. At 5 years of age, the patient had an uncomplicated case of chicken pox. For years the patient had had frequent

FIGURE 2 Case 2

upper respiratory infections, associated with rhinorrhea and postnasal discharge. During the year previous to examination, a diagnosis of sinusitis was made by an ear, nose and throat consultant.

On physical examination, the patient was found to be well developed. There was no evidence of cardiorespiratory distress, although there were a frequent moist cough and questionable cyanosis. Significant physical findings were dextrocardia, with no enlargement, arrhythmia or murmurs, moist and dry rales over both lower lung fields posteriorly and transposition of the abdominal viscera.

A conventional posteroanterior radiogram of the chest showed the dextrocardia to be associated with a generalized increase in the bronchial markings. On the left side, the cardiohepatic angle was obtunded by soft flocculent shadows. In the right lower lung field, there was evidence of peribronchovascular inflammatory change.

Lipiodol was instilled into the right lower lung field by Dr. Robert M. Lowman, radiologist of the Grace Hospital, New Haven, Connecticut. Under fluoroscopy a cylindrical dilatation of the second and third dorsal bronchi could be visualized (Fig 2).

One of the valuable byproducts of mass radiography in the control of tuberculosis is the detection of nontuberculous pulmonary disease. Gould²³

*This case is reported with the permission of Dr. W. D. Partlow, superintendent of the Bryce Hospital. It was correctly diagnosed on 35 mm film, being discovered during the conduct of a survey for tuberculosis.

formerly. Hence present control of diphtheria must be concerned not only with immunization of a wider age group than previously but also with the necessity of maintaining immunity once it has been established. In the application of procedures under these circumstances, several points deserve particular consideration.

Choice of immunizing agent. The antigenic superiority of toxoid over toxin-antitoxin has long been established¹⁸⁻²⁰. When the slight though real dangers of serum sickness from toxin-antitoxin²¹ and the inherent risk of administering a toxic preparation²² are also considered, there appears little justification for its continued use except under special circumstances. The principal choice thus narrows down to FT (fluid toxoid) versus APT (alum-precipitated toxoid). Both, when properly used, are extremely effective as judged by the production of a negative Schick test. Fraser and Halpern²³ and Volk and Bunney²⁵ found that about 95 per cent Schick reversals may be observed a few months after administration of two doses of APT or three doses of FT. It is possible that APT is slightly superior to FT, but the difference is considerably less than can be observed, for example, between good and poor batches of APT.^{9, 26, 27} The experience of recent years suggests that occasional or perhaps periodic reinforcing doses of toxoid are required to replace the stimulus no longer provided by the diphtheria carrier. Such repeated doses increase the possibility of allergic reactions to constituents of the toxoid, and it has been variously demonstrated²⁸⁻³⁰ that alum precipitation markedly enhances the capacity of toxoid and other antigens to produce reactions of hypersensitiveness. Thus, Fraser²⁴ warns against the possibility of obtaining undesirable anaphylactic reactions when immunity is reinforced by a subsequent dose, since APT is extremely effective in rendering guinea pigs sensitive and anaphylactic, the administration of a second or subsequent dose at long and irregular intervals may increase the danger of such reactions in man. Additional objections raised against APT are the greater frequency of local reactions,³¹⁻³³ the localization of smallpox vaccination at a site recently injected with APT³¹ and the difficulty of maintaining a uniform suspension, particularly in mass immunization.³⁴ It should be noted, however, that allergic reactions to APT are extremely rare and that studies suggest that similar reactions to tetanus toxoid can largely be ascribed to the presence of an obsolete ingredient in the medium rather than to the bacterial protein itself.³⁵ Moreover, APT has the definite advantage of requiring only two instead of three doses for adequate primary immunization. This may therefore prove to be the agent of choice wherever geographic, educational or administrative factors make it difficult to ensure completion of three doses, whereas FT may be preferred wherever the completion of a three-dose schedule

presents no major problem. With either agent, it should be possible to obtain a toxoid free of antigenic constituents other than those caused by the diphtheria bacillus itself, since Mueller et al.³⁶⁻³⁸ and others³⁹⁻⁴¹ have demonstrated that a potent FT or APT can be produced on a peptone-free medium. Such a medium has been used for the entire production at the Massachusetts Antitoxin and Vaccine Laboratory for over six years.

Preferred dosage and interval. There is no longer any justification for attempting immunization with one dose of APT or two doses of FT except in an emergency, although these inferior methods give better results than no immunization.^{42, 43} Both systems have had their vogue, and both are now generally discredited as being insufficient to produce an adequate, sustained immunity,^{24, 25, 43, 44} although Bousfield^{45, 46} and others maintain that, when diphtheria is prevalent, adequate results may be obtained with one dose of APT. The recent description of a diphtheria outbreak among a group of children, most of whom had received one dose of APT,⁴⁷ and similar experiences⁴⁸ testify that such a procedure does not protect effectively against intimate exposure to virulent bacilli. Proper immunization, therefore, is still based on two doses of APT or three of FT. Likewise, proper immunization depends on spacing the doses at least three weeks apart, regardless of which agent is used. The practice of giving successive doses of APT one week apart seems never to have arisen, but it is still widely supposed that an interval of a week is sufficient when FT is used, despite Ramon's⁴⁹ evidence to the contrary many years ago. Numerous recent studies have shown that a longer interval is also advantageous when APT is used.⁵⁰⁻⁵² Furthermore, experience with tetanus toxoid, pertussis vaccine, typhoid vaccine and other immunizing agents points to the advantages gained by lengthened intervals between doses.

Various British studies on APT immunization have recently reopened the question of the optimal size of dose.^{9, 26, 27, 45, 53} The evidence suggests that doses as small as 0.1 to 0.3 cc. are effective.⁹ These studies were for the most part carried out in areas where diphtheria was more prevalent than in the United States, also the subjects were not followed up with Schick tests later than four or five months after immunization. The results must therefore be re-evaluated before they can be judged in the light of American conditions and standards.

Results obtained with toxoid. As suggested above, the results obtained vary with many factors, among the most important of which is the interval between immunization and follow-up. Fraser and Halpern⁵⁴ have shown that three months after immunization with three doses of FT, a large number of previously susceptible children had over 0.02 unit of antitoxin per cubic centimeter of serum, this is more than five times the amount necessary for the production

MEDICAL PROGRESS

ACTIVE IMMUNIZATION

GEOFFREY EDSALL, M D *

BOSTON

THE continued extension of public-health and preventive medical activities, the need for new and massive immunization programs among the armed forces of the United States and other countries, and the corresponding impetus that the war gave to investigations concerning active immunization have in recent years produced an enormous mass of theoretical and experimental observations in this field.

In this review no attempt is made to cover any branch except active immunization as it applies to diseases existing in New England for which such immunization is of practical interest—that is, diphtheria, scarlet fever, tetanus, pertussis, typhoid fever, smallpox, influenza and rabies. Even within this range, the review is essentially incomplete, in so far as it omits many subjects that are now primarily of theoretical interest but on which important future trends in active immunization may depend. Such topics as the mechanisms of immunization, the immediate and late effects of hypersensitization and their underlying mechanisms, the so-called “interference phenomena” that have recently come to light—especially in the field of virus infections—and the significance of nonspecific protein reactions (among which may be included the recently publicized antireticular cytotoxic serum of Bogomolets¹) are inseparably related to active immunization but, for practical reasons, cannot be considered.

All the commercial laboratories and several of the larger state and municipal laboratories preparing biologic products for immunization operate under licenses from the Federal Security Administration, through the National Institute of Health of the United States Public Health Service. Such laboratories, which are regularly inspected by officers of the National Institute of Health, must, with few exceptions, submit samples and protocols of each batch of the product distributed, must clearly label the package in certain specified respects and must conform to certain minimum requirements governing safety and, generally, potency. Consequently, one may be reasonably certain that such products are not harmful and that, so far as practicable, their effectiveness is maintained above a specified minimum. Beyond these limits, however, the National Institute of Health recognizes that large areas exist

within which possible improvements in methods of production, testing and use may be found. Currently, continuing studies of all types of research, as well as extensive applications of biologic products to human patients by clinicians and public-health workers, guarantee that no product or method will remain static for long. Moreover, since epidemic disease knows no artificial boundaries, the advances in this field have been world wide, the material presented below has accordingly been drawn from almost as wide a range as the scope of the diseases in question.

Several general textbooks and reference books published in recent years have given considerable space to the preparation or the use of biologic products.²⁻⁶ Such texts are of great value for general information and reference. Each includes primarily topics of particular relevance to the text, and therefore each must be supplemented with data from other sources, to cover wider areas as well as to bring the information contained up to date. Current advances in the related subject of diagnostic skin tests have recently been reviewed.⁷

DIPHTHERIA

The decline in the diphtheria case and death rates, which began many years ago, has been greatly accelerated by the use of artificial immunization, so that within the last few years case rates of less than one hundredth of those sixty years earlier have been recorded, as in Massachusetts.⁸ This decrease has been accompanied by a tremendous decline in the carrier rates in artificially immunized communities, and hence in the frequency of naturally acquired stimuli to immunity, in turn apparently related to a widely noted decrease in the general level of immunity in certain sections of the population. Schick-test surveys among young adults or adolescents in England, Canada, Australia and the United States have shown that 50 to 60 per cent are susceptible to diphtheria,⁹⁻¹⁶ in contrast to the incidence of 20 to 25 per cent of positive reactions formerly reported in these age groups.¹⁷ Thus a growing reservoir of young adults susceptible to diphtheria appears to exist. A parallel consequence of the reduced prevalence of diphtheria bacilli is that artificially induced primary immunity is likely to wane and disappear more rapidly than

*Director, Division of Biologic Laboratories, Massachusetts Department of Public Health; instructor in bacteriology and immunology, Harvard Medical School.

of infants whose mothers are not immune. Where diphtheria is prevalent, its occurrence in infants represents a real danger, for it can readily produce an atypical and overwhelming infection.⁹⁶ Liebling, Youmans and Schmitz⁹⁷ have offered a partial solution to this problem by antenatal immunization of Schick-positive mothers. A small group whose response was followed beyond the neonatal period, however, indicated that the immunity thus transferred to the infants was even shorter lived than the inherited natural immunity.⁹⁸

Combined immunization with diphtheria toxoid and other agents is discussed below, under tetanus, pertussis and typhoid fever, since such combinations are usually designed to incorporate other agents into an established procedure for diphtheria immunization.

SCARLET FEVER

The many factors involved in the medical and administrative control of scarlet fever have recently been thoroughly reviewed.⁹⁹ There is fairly general agreement that streptococcal toxin prepared, standardized and used according to the methods prescribed by the Dicks¹⁰⁰ prevents the development of clinical scarlet fever in a great majority of persons exposed. In this respect Anderson's¹⁰¹ review of a decade ago is fully valid today. Place,¹⁰² Lucchesi,¹⁰³ Toomey¹⁰⁴ and others have confirmed the numerous earlier reports that immunization according to the Dick method practically abolishes the occurrence of scarlet fever among nurses working in contagious wards. Graham¹⁰⁵ reports that follow-up Dick tests were negative in 86 per cent of 50 private patients tested five to ten years after immunization, and in 84 per cent of 30 subjects thirteen to fifteen years after inoculation. Little¹⁰⁶ observed 63 cases of scarlet fever among 6982 immunized subjects observed over a seven-year period, in contrast with 915 cases among 8063 unimmunized persons — an attack rate of 0.9 per cent in the former as against 11.3 per cent in the latter.

Such an effective procedure would have been universally accepted long ago if it did not have definite drawbacks. Foremost among these are the frequency and severity of the reactions produced by the dosage of the subcutaneous injections of toxin recommended by the Dicks, which are usually 650, 2500, 10,000, 30,000 and 100,000 to 120,000 STD (skin test doses) at weekly intervals. There is still, as Anderson stated,¹⁰¹ surprising unanimity of opinion regarding the severity of reactions to toxin injections, most observers mentioning severe reactions in as many as 10 or 15 per cent of cases. Jacobs and Orris¹⁰⁷ report an incidence of 28 per cent of moderate or severe reactions, including nausea, vomiting, fever and a rash comparable to that of mild scarlet fever itself. Less frequent, but perhaps highly significant, is the occurrence of joint manifestations,¹⁰⁸ which have been found to exhibit

a high degree of association with a history or signs of rheumatic fever. Such a relation possibly explains the reported fatal reaction occurring in a thirteen-year-old boy following an initial 500 STD of scarlatinal toxin.¹⁰⁹ At all events, it becomes difficult to justify the widespread use of a procedure that may cause reactions such as those described. Moreover, there is considerable doubt whether the scarlatinal rash is produced by only one antigenic type of toxin.¹¹⁰ Hence, with the various factors concerned taken into consideration, it has been authoritatively stated that information is at present sufficiently convincing to render immunization against scarlet fever as a routine or community-wide practice under official auspices inadvisable until a more suitable antigen becomes available.¹¹¹

Nevertheless, certain groups must be immunized, particularly physicians, nurses and ward attendants likely to come in contact with cases of scarlet fever. Also the relatively high incidence of susceptibility among young adults, as evidenced by the Dick test or by clinical experience, can be of serious concern to military establishments and in civilian communities during high prevalence of the disease. Many attempts have therefore been made to overcome the difficulties encountered with the standard immunizing procedure by modifying the dose, the administration route or the antigen itself. Howie¹¹² employed a dosage schedule widely used in Canada (330, 1000, 2300, 5000 and 10,000 STD) in the immunization of over 8000 school children at the onset of an epidemic of scarlet fever in Windsor, Ontario, five months later, 89 per cent of a representative sample of the group were Dick negative, and statistical data indicated that the epidemic had been checked, in contrast to the neighboring city of Detroit, where it continued unabated. Glazier¹¹³ immunized 340 children over a period of years with seven weekly doses of 650, 2500, 5000, 10,000, 25,000, 55,000 and 110,000 STD respectively, reactions occurred after only 7 per cent of the injections, and Dick tests (one week after the last dose) were negative in 265 out of 268 children tested. None of the 340 patients subsequently developed scarlet fever.

Others have tried intranasal, percutaneous, intracutaneous and oral administration of the toxin, Graham has reviewed most of these studies.¹¹⁴ The intracutaneous route has given excellent early results in some hands,¹¹⁵⁻¹¹⁸ although as many as ten doses were required in individual cases to produce a negative Dick test.¹¹⁷ Late follow-up Dick tests, however, indicated that a large number of the patients had reverted to the Dick-positive state.^{107, 117} As indicated elsewhere, there is increasing reason to believe that the intracutaneous route is probably not dependable for routine primary immunization, although it can doubtless be used successfully in carefully handled individual cases. Results with the percutaneous, intranasal and oral routes, including 59 of Graham's patients given toxin intranasally, in-

of a negative Schick test,⁵⁵ which in turn is generally correlated with resistance to diphtheria.⁷ A year later 3 per cent and three years later 8 per cent of the group were Schick positive, whereas five years later 34 per cent had reverted to the Schick-positive state, and the average serum antitoxin titer was only 20 per cent of the maximum obtained shortly after immunization.⁵⁶ A more recent study indicates that among young adults the relapse rate may be as high as 20 per cent in one year.⁵⁷ Thus, the protection against diphtheria observed in any large group decreases in proportion to the interval since inoculation. Nevertheless, the clinical protection afforded by toxoid immunization is impressive. With few exceptions⁵⁸⁻⁵⁹ the incidence of diphtheria among immunized persons averages about 10 to 15 per cent that among nonimmunized controls.^{43, 60-62} Moreover, diphtheria is usually milder in inoculated than in unimmunized persons.⁶²⁻⁶⁶ Occasional cases occurring in previously immunized patients, however, sometimes arouse doubts concerning the efficacy of immunization in general, it is only by adjustment of the observed case rates to the relative numbers of the immunized and unimmunized persons, as Gibbons⁶⁰ has done, that the high degree of protection actually achieved by immunization is made clear.

Immunization of adolescents and adults with toxoid In virtually all the usual immunization programs, diphtheria toxoid is the only agent used. The provision of toxin-antitoxin mixture in Massachusetts for group immunization is being continued temporarily because of long familiarity with this agent — particularly for adult immunization — and the admitted difficulties arising from the relatively frequent reactions experienced by adolescents and adults receiving toxoid in the routine dosage. Extensive experience in Canada and several states in this country, however, indicates that reactions can largely be avoided by the inoculation only of persons who are Schick positive, the performance of the Moloney test, using 0.1 cc of diluted toxoid, on the Schick positives⁶⁶⁻⁶⁸ and the administration of divided doses of toxoid or diluted toxoid to subjects showing positive Moloney reactions.⁶⁹ The usual initial dose in older subjects is 0.1 cc^{70, 71} which has in fact on occasion been substituted for the Moloney test.^{72, 73} Recent observations suggest that immunization should be withheld from persons exhibiting any reaction to the Schick control test,¹⁶ which should therefore always be employed in subjects tested in these age groups, since such reactors almost always possess either actual⁵⁵ or latent¹⁶ immunity and usually show marked reactions to toxoid.⁷⁴ Furthermore, Wishart et al.⁷⁵ and Paschlau⁷⁶ have noted a direct correlation between severity of reaction and degree of immunity, so that in group immunizations one may safely leave the toxoid reactors with a single stimulus from the Schick or Moloney test,

or both. This principle has been followed on a large scale in military establishments.⁷²

Other immunization routes Numerous workers have experimented with intranasal immunization with toxoid by drops⁷⁷⁻⁸⁰ or sprays.⁸¹ As a procedure for primary immunization, the intranasal route appears less potent than the parenteral, whereas its use for reimmunization is likely to lead to severe and peculiarly uncomfortable reactions in persons who have acquired a sensitivity to toxoid. Percutaneous immunization⁸² has been tried without success, and intradermal immunization⁸³⁻⁸⁶ has also been employed, with better results in some hands⁸⁶ than in others.⁸⁶ As might have been expected, reactions were more marked following intradermal administration of APT than when FT was used.^{85, 88}

Bousfield,⁸⁷ who⁸⁸ has explored various unusual routes of immunization against diphtheria, has recently suggested the use of toxoid pastilles to be sucked like hard candy. He reports that evidence for their effectiveness in primary immunization is lacking, but that they elicit an effective booster response and do not provoke local or general reactions. Finally, mention should be made of the protamine-toxoid combination developed by Ross,^{89, 90} which appears to be remarkably high in potency and which produces little reaction. Both preparations warrant further study.

Reimmunization The importance of reimmunization at some time subsequent to the primary immunization is apparent from the findings cited above. The dose required is often exceedingly small. Twenty years ago Glenn⁹¹ called attention to the booster effect frequently observed after a Schick test performed with material containing about one fifteen hundredth as much antigen as the corresponding volume of the average toxoid. Wishart et al.,⁷⁵ Volk et al.,⁹² Wilkey⁹³ and others have presented impressive evidence of the rapid and powerful effect of a booster dose of toxoid in persons with previously acquired immunity. The rises observed may be tremendous (over seven thousand times the minimum protective titer) and long lasting (three months or more).¹⁶ Nevertheless, adequate responses were not recorded in some subjects until about a week had elapsed,⁷⁵ so that the method is not completely dependable as an immediate protective measure following exposure to diphtheria. For the routine maintenance of group immunity, however, it has quite properly been widely advocated as a periodic health measure, particularly in localities where the natural incidence of diphtheria is too low to provide the necessary booster effect.⁹⁴

Immunization of infants It has long been taught⁹⁵ — and is doubtless generally true — that the best time for immunization of infants is after the first six months, because prior to this period the passively inherited maternal immunity interferes with the active effect of toxoid. Yet such a postponement leaves unprotected the currently increasing number

out. The wound may be so slight that medical aid is not sought or injury is not suspected. Antitoxin may not be readily available, the child may be allergic or may have received serum previously, and the ever-frequent serum sickness is always possible. Such considerations may influence the decision to take a chance and withhold serum.

The introduction of tetanus toxoid as an active immunizing agent offered a means of prevention that obviated many of these objections. The development and use of tetanus toxoid have been reviewed by Jordan and Halperin,¹⁴² Newhouse¹⁴³ and others. A great many investigators have clearly established the capacity of tetanus toxoid to produce significant and presumably protective serum antitoxin levels in human beings. So many individual variables — such as age of patient, kind of immunizing agent, size of dose, interval between doses and accuracy of titrations — have been introduced that evaluation of the data in such studies is extremely difficult. Furthermore, the problem of interpreting the reported results is illustrated by such passages as the following:

From the data it was deduced that when the initial tests were done within two months of giving the combined toxoids and the comparative tests showed the antitoxin values to be higher, the same or even lower after the respective third and second doses, then the tests performed from seven to twelve months later revealed not only that the drop of the titre was retarded after the third dose but that the antitoxin values were also higher.¹⁴⁴

It is possible, however, within certain limits, to define the principal results by means of the following considerations:

Number of doses required. One dose produces almost no detectable immunity but prepares the subject to react effectively to subsequent doses.¹⁴⁵ Acceptable results are obtained by the administration of three doses of FT (fluid toxoid) or two doses of APT (alum-precipitated toxoid). Ramon¹⁴⁶ has from the beginning recommended three doses of fluid toxoid, and the inadequacy of two doses of this agent has recently been confirmed.¹⁴⁷

Choice of interval between doses. For satisfactory results successive doses at least two weeks apart,¹⁴⁶ and preferably four weeks apart, are necessary. Peshkin,¹⁴⁸ Gold¹⁴⁹ and others have shown that excellent results are achieved even with intervals as long as two years between doses of APT. The limit to such extended intervals appears to be determined only by the period during which one can afford to wait before obtaining adequate immunity.

Choice of product. The principal advantages and disadvantages of each form of tetanus toxoid are essentially the same as those pointed out above for diphtheria toxoid. Dose for dose, APT is more effective than FT,¹⁵⁰⁻¹⁵² although the data in some cases are not properly comparable. The use of APT by the United States Navy and FT by the United States Army during the war should provide an un-

paralleled basis for comparison between the two, if the available data are ever analyzed.

Response to primary immunization. Practically all workers have observed marked variation in individual responses to primary immunization and have found occasional subjects in whom no detectable response appeared. In general, however, as with all immunization procedures for which accurate data are available, the antibody titer following primary immunization rises slowly to a maximum and then falls, at first rapidly and later more slowly, for as long as it can be detected. Obviously, the interpretation of results depends considerably on the interval chosen for the test. The actual interval between completion of immunization and development of a presumably protective antitoxin titer has been variously observed¹⁵³⁻¹⁵⁵, significant levels have been noted, however, as early as two weeks after immunization.

Protective level of antitoxin. Various workers have attempted — by analogy with titers observed following passive immunization¹⁵⁶⁻¹⁶¹ or by observing the titers in guinea pigs that were associated with protection against tetanus toxin¹⁵⁵⁻¹⁵⁶ or spores¹⁵⁷⁻¹⁶² — to estimate the level of antitoxin that will protect against clinical tetanus. These and other estimates range generally from 0.01^{148, 155-157} to 0.1 unit,¹⁴⁰⁻¹⁵⁹ but are of little practical value until they can be correlated with clinical experience, which has yet to be done.

Clinical evaluation. Massive clinical experience, although not correlated with serum antitoxin levels, has provided extensive statistical material for evaluating the efficacy of toxoid. Immunization of 40,000 horses in the French Army reduced the tetanus deaths in this group from the previous level of 50 to a single death.¹⁶³ In the retreat from Dunkirk, no cases of tetanus occurred among British soldiers protected with toxoid.¹⁶³ Among the more than 10,000,000 soldiers in the United States Army during World War II, there were only 3 known cases of tetanus in soldiers whose immunization record showed that the full immunization schedule had been completed.¹⁶⁴ The somewhat less perfect record in the British Army¹⁶⁵ may reasonably be ascribed to its policy of omitting the booster dose after injury and recommending antitoxin instead. Boyd¹⁶⁶ minimizes the value of the booster dose, arguing that it cannot be effective in less than ten days and that the infection itself serves as a booster after this interval in persons who have received primary immunization. It has been shown in animals,¹⁶¹⁻¹⁶² however, and in man,^{144-153, 154} that a marked response to toxoid appears by the fifth to seventh day. Moreover, this response is earlier and more effective in animals than the booster effect of infection itself.¹⁶¹⁻¹⁶² Boyd lists 22 cases of tetanus (with 11 deaths) among soldiers or others who had been protected with two or more doses of toxoid. Out of 15 soldiers in the British, Indian or Dominion

licated on the average a lasting immunity of about 60 or 70 per cent, although better results may be found in early follow-up Dick tests. Several years ago the Dicks¹¹⁹ reported that 93 per cent negative tests were obtained following the oral administration of over 8,000,000 STD in enteric-coated tablets. The wider development of this method has been hampered by the expense of preparing this quantity of toxin in powdered form and by the difficulty of ensuring its proper absorption. No recent reports on this interesting method have been noted.

Attempts have been made to reduce the reactions following scarlatinal toxin injection by purifying the crude toxin. Stock,¹²⁰ Veldee¹²¹ and others have employed various methods for separating the toxin from the other constituents of the medium, it is in fact possible to prepare toxins of extremely high purity by such means. In these preparations relatively few side reactions are caused by impurities, but their primary toxicity is unchanged. Hence, other means of preparing a tolerable product must be resorted to. Several workers have prepared toxin precipitated with alum¹²² or adsorbed on aluminum hydroxide.¹²³⁻¹²⁵ Menten et al.,¹²⁵ who for unexplained reasons refer to their product as a "toxoid," found that it yielded a higher Dick-negative rate than that observed in other groups immunized with a fluid toxin, and that it caused fewer reactions. The possibilities of this procedure call for further study.

Veldee et al.¹²⁶ have prepared a tannic-acid-precipitated, purified toxin that, modified slightly, was used in an extensive field study, comprising over 41,000 person-years of observation in an immunized group and a carefully analyzed and much larger control group. It was demonstrated that approximately 87 per cent of Dick-positive reactions in children before immunization became negative and remained so for four years after immunization with three intradermal injections of 750, 3000 and 10,000 STD of this toxin at intervals of two weeks. Similarly, the incidence of scarlet fever among the entire immunized group was only about one fifth that in the control group. Reactions were rare, and no child or parent refused to complete the entire course. The study was carried out with very thorough and accurate statistical and epidemiologic controls. The results appear highly promising, and it is hoped that, since a tannic-acid-precipitated toxin has been approved by the Council on Pharmacy and Chemistry of the American Medical Association,¹²⁷ further trials of this preparation will be forthcoming.

Attempts to produce a scarlet-fever toxoid have been carried out by numerous workers. Following the encouraging results obtained by Veldee,¹²⁸ a formalinized toxin was given extensive trial in Massachusetts. A preliminary report by Anderson¹²⁹ on the results with such a preparation, administered in doses of 0.1, 0.5 and 1.0 cc subcutaneously at intervals of three weeks, showed that approximately 52 per cent Dick reversals were obtained, and that

the number of cases of scarlatina in the immunized group was only about 60 per cent of that to be expected from analysis of the control group. Reactions to the product were few and mild, and only 11 per cent of 9200 children failed to complete the course of three injections. Results obtained with subsequent and more potent batches of toxoid have probably been better than Anderson's figures indicate.¹³⁰ Unless strikingly improved immunization can be produced with such a preparation, however, it will probably be abandoned in favor of one with a higher antigenic potency. Since the Scarlet Fever Committee patent expired four years ago and since the restrictions on the free development of scarlet-fever prophylactics other than the Dicks' immunizing toxin have accordingly been removed, it can be expected that active and productive research in this heretofore relatively static field will proceed vigorously to the development of a satisfactory prophylactic agent.

TETANUS

Tetanus has always been a serious menace to war casualties, but even under the conditions of Western civilization in peacetime the possibility of its occurrence must constantly be borne in mind. Adequate cleaning and débridement of wounds remains the first defense against tetanus. Treatment of wounds can never be relied on to prevent all cases, however, for as many as 50 per cent may not be traceable to a known injury^{131, 132} and many other cases follow neglect of such minor infections as those produced by a splinter. Since the tetanus bacillus is found even in city streets,¹³³ the possibility of infection with this organism is ever present.

Until recent years protection against tetanus was obtained largely through the prophylactic use of tetanus antitoxin. MacConkey¹³⁴ reviewed the experience with this agent in World War I and called attention to the occasional failures to obtain protection. Failures are also recognized in civilian experience, of the 146 tetanus cases reported by Dietrich,¹³¹ Klopp¹³⁵ and Kirtley,¹³⁶ 11 patients had received prophylactic antitoxin, and 8 of the 11 died. Among a group of 15,000 to 20,000 casualties of the blitz of 1940 in England, 7 definite cases of tetanus occurred, in all but 1 of which 1000 to 1500 American units of antitoxin had been administered shortly after injury.¹³⁷ In the retreat from Dunkirk, 8 cases occurred in wounded soldiers who had never received toxoid and who had to rely on antitoxin prophylaxis.¹³⁸ Such irregularities appear to result mostly from the varied rate at which the antitoxin is eliminated from the blood stream.^{44 139-141} Thus the results obtained with prophylactic antitoxin are undependable, the more so because tetanus infection may exhibit a prolonged time lag between its introduction and its activation. Moreover, the disadvantages of antitoxin for prophylaxis are not limited to its undependability, as Bigler and Werner⁴⁴ have pointed

The best type of schedule might well be adapted from that of the United States Army³⁵ primary immunization with two doses of APT or three of FT at intervals of one month or longer, followed by at least one recall dose six to twelve months later and another recall dose after any injury of the sort that is known to involve the risk of tetanus infection. The available evidence suggests that active immunity is acquired within two weeks after the primary immunization is completed, but it is nevertheless wise to heed the warning of Tuft⁴² and carry out immunization so far as practicable in advance of possible exposure to tetanus. The practice of administering prophylactic antitoxin routinely following accidents or injuries will have to be greatly modified in civilian practice. When such injuries occur to persons who are known to have been actively immunized, such as all veterans of World War II, emergency prophylaxis should be obtained by administering a booster dose of toxoid.¹⁹²

forces, 10 had received three or more doses. Only 4 men had been given four, and 2 had been given five doses. Since the standard procedure in the United States Army calls for at least four and usually five doses of toxoid as well as the emergency booster dose at the time of injury, the cases of tetanus reported here and elsewhere¹⁶⁶⁻¹⁶⁸ in British and Colonial troops do not, as has been suggested,^{169, 170} provide a valid criterion of the efficacy of tetanus toxoid prophylaxis performed according to current American practice.

The booster dose. On receiving a booster dose of toxoid, a previously immunized person exhibits a marked and rapid rise in serum antitoxin titer.^{142, 144, 146, 150, 152, 171-173} Hence it has been generally advocated in this country that recall doses be given periodically, to restore the immunity level, which gradually falls after primary or later stimuli, and after injury to produce a maximal antitoxin level at the time of the greatest danger of toxin absorption. Some writers have assumed that the absorption of tetanus toxin in itself provides a sufficient booster effect,¹⁵⁰ but the available evidence indicates that tetanus infection does not act as a primary stimulus to antitoxin production^{152, 159} and gives a secondary stimulus too late to be dependable.^{161, 162} Therefore, until it is possible to define what constitutes a protective serum antitoxin level and to perform a simple test for the presence of this degree of protection, the only way to assure the maximum degree of protection is to make the most of the booster dose, by giving supplementary injections of toxoid following known injuries and by giving periodic doses to ward off the tetanus infections that can occur after unnoticed injuries. The efficacy of the booster dose does not appear to decrease as the interval between it and the primary immunization increases. Peshkin has obtained excellent booster responses one,¹⁴⁴ two,¹⁷⁴ three¹⁷⁵ and four¹⁷⁶ years after primary immunization. Furthermore, with each subsequent recall dose, the antitoxin titer usually rises higher and remains elevated longer.^{176, 177} Yeazell and Deamer¹⁴¹ employed intradermal toxoid successfully for the booster dose. It has been shown in animals that the booster response is but little affected by cold, restricted diet or overwhelming infection.¹⁷⁸ The only limiting factor in utilizing the booster effect appears to be the time interval between injection and response. The occasional subject whose response is slow might conceivably cause some anxiety, but clinical experience, as in the United States Army, strongly indicates that the rate of response to a booster dose is adequate. Finally, since the titer achieved following a booster dose remains elevated for several months,^{144, 154, 174-176} frequent repetition of doses, such as those that must be relied on in prolonged antitoxin prophylaxis, is not necessary.

Other routes than the subcutaneous for administration of tetanus toxoid have been employed rela-

tively little. Gold¹⁷⁹ and Sordelli et al.¹⁸⁰ gave booster doses intranasally, with apparently satisfactory results. Friedman and his associates¹⁸¹ employed intradermal inoculations, but the results were decidedly less satisfactory than those obtained by the usual subcutaneous route.

Active-passive immunization. No clear-cut answer has yet been given to the dispute regarding combined active and passive immunization. In a patient exposed to tetanus, never previously immunized and requiring prophylactic antitoxin, one school of thought maintains that simultaneous commencement of active immunization with toxoid is ineffective because of the presence of excess antitoxin.¹⁸¹ Another school has for over twenty years maintained that simultaneous active-passive immunization can be successfully practiced.^{182, 183} The official policy of the United States Army has been to administer antitoxin prophylaxis only if an initial course of active immunization has not been completed and to start simultaneous active immunization.³⁵

Allergic reactions. Such reactions, which have been reported to both FT and APT,^{35, 151} have been amply reviewed by Long,³⁵ who showed that the urticarial type resulted from the presence of Witte or Bernal peptone in the toxoid medium. The elimination of these ingredients from subsequent preparations has apparently virtually eliminated this type of untoward reaction. One of Swartz's¹⁸⁴ cases, however, may have represented a sensitivity to some ingredient in the toxoid other than peptone. The studies of Mueller¹⁸⁵ and of Taylor¹⁸⁶ on the production of toxin on simplified media and the recently reported successful purification of tetanus toxin¹⁸⁷ should lead to the preparation of toxoids possessing but a minimal capacity to induce sensitization phenomena. Meanwhile, many reports of successful and virtually reaction-free tetanus toxoid immunizations, including large numbers of allergic subjects,^{140, 141, 144, 148, 154, 174-176, 180, 188, 189} suggest that the danger of allergic reactions in atopic subjects is no greater than that in normal persons—in marked contrast to the danger of using antitoxin in such subjects.

Indications for immunization. The indications for the employment of tetanus toxoid have been well summarized,¹⁹⁰ as follows: in allergic persons or those with known sensitivity to horse serum, in farmers, hostlers, veterinarians, horsemen and others experiencing relatively frequent opportunity for contamination of wounds with tetanus spores, and by and large in children, among whom the incidence of infected wounds is high and many unnoticed infections may result in tetanus. The combination of tetanus toxoid with diphtheria toxoid for immunization of children therefore appears wise not only in private practice but also as an adjunct to diphtheria-control programs.

The best type of schedule might well be adapted from that of the United States Army³⁵ primary immunization with two doses of APT or three of FT at intervals of one month or longer, followed by at least one recall dose six to twelve months later and another recall dose after any injury of the sort that is known to involve the risk of tetanus infection. The available evidence suggests that active immunity is acquired within two weeks after the primary immunization is completed, but it is nevertheless wise to heed the warning of Tuft¹¹ and carry out immunization so far as practicable in advance of possible exposure to tetanus. The practice of administering prophylactic antitoxin routinely following accidents or injuries will have to be greatly modified in civilian practice. When such injuries occur to persons who are known to have been actively immunized, such as all veterans of World War II, emergency prophylaxis should be obtained by administering a booster dose of toxoid.¹⁹²

NEW HAMPSHIRE MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND FIFTY-FIFTH ANNIVERSARY

House of Delegates, May 13 and 14, 1946

THE House of Delegates convened at the Hotel Carpenter, Manchester, on May 13, 1946, at 7 30 p m., with Speaker Deering G. Smith presiding. The following members answered the roll call:

The President, *ex-officio*
 The Vice-President, *ex-officio*
 The Secretary-Treasurer, *ex-officio*
 Samuel Feiner, Ashland
 Earl J. Gage, Laconia
 Francis J. C. Dube, Center Ossipee
 W. J. Paul Dye, Wolfeboro
 Albert C. Johnston, Keene
 James M. Ballou, Keene
 Marjorie B. Parsons, Colebrook
 Francis M. Appleton, Gorham
 Howard N. Kingsford, Hanover
 Israel A. Dinerman, Canaan
 Leslie K. Scamore, Hanover
 Robert E. Biron, Manchester
 George C. Wilkins, Manchester (alternate for Samuel Fraser)
 Loren F. Richards, Nashua
 Robert R. Rix, Manchester
 Deering G. Smith, Nashua
 Frank J. McQuade, Franklin
 William P. Clough, Jr., New London
 Philip M. L. Forsberg, Concord
 Willard C. Montgomery, Epping

Samuel T. Ladd, Portsmouth
 Robert W. Tower, Plaistow
 William R. Latchaw, Somersworth
 Raymond R. Perreault, Rochester
 Addison Roe, Newport
 B. Read Lewin, Claremont

The Speaker declared a quorum present, and appointed the Credentials Committee as follows: Drs. Appleton, Latchaw and Feiner. To the Committee on Officers' Reports, he appointed Drs. Lewin (chairman), Biron and Montgomery. To the Committee on Communications and Memorials he appointed Drs. Dinerman, Tower and Perreault. To the Committee on Nominations, he appointed Drs. Richards (chairman), Gage, Forsberg, Dye and Ladd. For the Committee on Credentials, Dr. Appleton reported that the credentials were in order.

On motion duly made and seconded, it was voted to omit the reading of the previous minutes, because of the publication of the proceedings.

On motion duly made and seconded, it was voted to dispense with the reading of the reports of the councilors, since they will be published in the *Transactions*.

The Secretary-Treasurer, Dr. Carleton R. Metcalf, presented his report, as follows:

MEMBERSHIP, DECEMBER 31, 1945

PAID	
Belknap County	23
Carroll County	9
Cheshire County	17
Coos County	21
Grafton County	58
Hillsborough County	98
Merrimack County	53
Rockingham County	46
Strafford County	29
Sullivan County	14
Not in County Society	3
	371
UNPAID	
Life members	18
Honorary members	5
Members in service and delinquents	134
	157
	528

The total membership on December 31, 1944, was 546

Balance, January 1, 1946	107 24
	\$3240 22

The total membership on December 31, 1945, was 528. This is a decrease of eighteen over the preceding year.

The following officers died during the year 1945: Clifton S. Abbott, Laconia; Henry O. Smith, Hudson; Herbert L. Taylor, Portsmouth; and Richard E. Wilder, Whitefield.

Although no money was added to the Benevolence Fund from the annual dues during 1945, a donation was received from the Hillsborough County Auxiliary. Ninety-three dollars for the National Physicians Committee was received from the following auxiliaries: Merrimack County, Strafford County and Sullivan County.

In accordance with instructions from the House of Delegates, \$40.00 was given to the Cancer Committee. The question of outpatient psychiatric care in New Hampshire was referred to the Committee on Mental Hygiene, with the request that it consider the matter and report at this meeting.

A report on the New Hampshire Physicians' Service, or Blue Shield, which was inaugurated and sponsored by the House of Delegates, will be given by its president, Leslie K. Sycamore.

I recommend that we drop the following two standing committees this year: the Committee on O. P. A. Assistance and the Committee on Medical Preparedness. On the other hand, we should add one new standing committee because during the last year the Council of the State Medical Societies of New England has been rejuvenated. This council held three or four meetings and considered medical matters that pertained to all the New England states, particularly matters of national legislation. Dr. Robinson, Dr. Sycamore and I attended two meetings as unofficial delegates from New Hampshire and we gave the Council \$100.00 from the treasury of this society to help pay the running expenses. I suggest that the House of Delegates approve this fee and apportion \$100.00 each year for the same purpose and that the Committee on Nominations recommend a standing committee of three for membership on this council. Now that many of the members of this society have returned from the Armed Services, I also suggest to the Committee on Nominations that our various committees be strengthened by the appointment of a due proportion of younger men and of veterans. The Committee on Nominations should also note that Dr. Fitch has resigned as alternate delegate to the American Medical Association.

The annual meeting this year is limited to one day for two reasons: it is difficult to get hotel accommodations to stay overnight in Manchester, and a one-day meeting is less expensive than a longer meeting and we have been "in the red" for the last few years. I hope, however, that next year and thereafter we may return to our former plan of having the annual meeting last for two days. Some members of the Society have suggested that the meeting next year be held during June at one of the resort hotels, for example, a hotel at Portsmouth or one at Sunapee. A scheme of this sort has been followed for many years by the Maine Medical Association, whose members seem to like it. I recommend that the House of Delegates give it consideration.

In view of our somewhat embarrassed financial position, I recommend an increase in the annual dues of the Society. The present by-law reads "an assessment of \$6.00 per capita on the membership of the component societies is hereby made the annual dues of this society." If this assessment were increased to \$9.00, we should be able to carry on much better in an era in which expenses have slowly but surely become greater. Such an increase would presumably mean that each member of the county society would pay \$10.00, of which \$1.00 would be retained in the county and \$9.00 turned over to this organization. I have referred this matter to the Committee on Amendments. If it meets with the approval of this committee and your approval, the amendments should first be made in the House of Delegates and then ratified by each county society.

It is of interest to note that the Vermont State Medical Society has recently raised its annual dues to \$20.00, so that the increase that I have suggested seems relatively modest.

At the present time, the *New England Journal of Medicine* has been sent to each of our members once a month. Recently the *Journal* has suggested a modification of the arrangements as follows:

Either one of two arrangements is possible. The first is to send all issues of the *Journal* to the members of your society at a charge of \$2 50 for the current year. This, of course, would probably mean an increase in the annual dues of \$1 50. On the other hand, it seems likely that your members would derive a reasonable amount of benefit. The second is to continue with the present arrangement so far as all members of your society are concerned, but to permit any member to subscribe individually for all issues at an extra cost of \$1 50.

So far as the future is concerned, the rate of \$2 50 cannot be guaranteed. It seems reasonably certain, however, that there will not be an appreciable increase in cost, and if the circulation continues to increase and the advertising revenue is maintained, it might well be lowered.

At the present time the Society pays the *New England Journal of Medicine* \$1 00 a year for each member.

I should recommend the second alternative continue the present arrangement, but permit any member who wishes all issues to procure them by sending a check of \$1 50 directly to the *Journal*.

At the time this report is being written, the Wagner-Murray-Dingell Bill is being considered by the Committee on Education and Labor of the United States Senate. In accordance with the instructions passed by the House of Delegates, the Committee on Public Relations has been active in opposing this legislation.

Dr Robinson and I spent two days last February at a meeting of the National Physicians' Committee in St. Louis, where this and other federal legislation was thoroughly discussed. Here in New Hampshire, through the press and through personal contacts with various groups, we have tried to present the point of view of the Society, and many of these groups have co-operated with us in expressing their disapproval to our Congressional delegation. The end result is that as this report is written Senator Bridges, Congressman Adams and Congressman Merrow have stated that they would vote against the present Wagner Bill. Senator Tobey has been noncommittal.

On motion duly made and seconded, it was voted that the report of the Secretary-Treasurer be referred to the Committee on Officers' Reports.

Dr Lewin, chairman of the Committee on Officers' Reports, then stated that the Committee on Officers' Reports had recommended that the Nominating Committee create a new standing committee of three members, to be called the Committee of New England Medical Societies. He moved the adoption of this portion of the report. The motion was duly seconded.

The President expressed some doubt whether a new committee could be created by the Nominating Committee, since this was a matter of the by-laws of the Society and would require an amendment.

Dr Dye stated that the various standing committees came under the by-laws and the constitution, and that such a motion could therefore be recommended one day, put on the table that night and voted on the following day. He recommended such an amendment.

The Speaker requested the Secretary's opinion.

The Secretary replied that it was much easier to have all the committees on the same basis, and that they could be changed when necessary.

The President stated that he saw no reason why a special committee could not be appointed.

The Speaker asked for the motion again.

Dr Lewin moved that the House of Delegates instruct the Nominating Committee to create a new

standing committee of three members, to be called the Committee of New England Medical Societies.

Dr Dye moved that Chapter VIII of the by-laws be amended to include the committee recommended by the Committee on Officers' Reports. This motion was duly seconded.

Dr Lewin moved that the House of Delegates approve the \$100 00 given to the Council of the State Medical Societies of New England during this last year. This motion was duly seconded and carried.

Dr Lewin then moved that \$100 00 be appropriated for the Council of the State Medical Societies of New England this year.

This motion was duly seconded and carried.

Dr Lewin stated that the Committee on Officers' Reports had reached no conclusion regarding the site of future meetings. He recommended open discussion by the delegates.

Dr Sycamore stated that the delegates from Grafton were instructed to change the meeting place next year and asked whether such a decision were the province of the Program Committee.

The Speaker replied that the matter was one for decision by the House of Delegates.

Dr Sycamore moved that the House of Delegates be empowered at least to investigate another site for a meeting for next year and to adopt another site if a suitable one were available.

The Secretary observed that the situation has been complicated by transportation and by hotel accommodations, with practically no rooms available in Manchester. If a two-day meeting were held, the members who lived at a distance would probably have to come for only one day. The thought in suggesting this matter was that the Society could meet in some place like the Wentworth in Portsmouth. He further stated that the Wentworth advertises for conventions, which they can accommodate any time after June 1. He added that the housing problem would be solved at the Wentworth.

The Speaker asked if there was any further discussion on this subject.

Dr Ladd believed that the Wentworth would be a desirable place for the meeting.

The Speaker called attention to the fact that the by-laws state that the Society shall hold an annual session, during which there shall be held daily not less than two general meetings open to all registered members, delegates and guests, and that the place for holding such annual session shall be fixed by the House of Delegates, and the date by the President and the Secretary-Treasurer.

Dr Wilkins moved that the next meeting be held in Portsmouth at the Wentworth.

The motion was duly seconded by Dr Dye.

The Secretary suggested that power be given to someone to select a place, so that if the Wentworth burned down a special meeting would not have to be called.

Dr Wilkins accepted the amendment.

The Speaker asked for the opinion of those who wanted a two-day meeting. There was a unanimous showing of hands. He then stated that the motion before the House was that the next meeting of the Society should be held at the Hotel Wentworth in Portsmouth, and that if that site were not available, the President, together with the Vice-President and the Secretary, would select the site. The motion was carried.

Dr Lewin, for the Committee on Officers' Reports, moved that the present arrangement, namely, that the Society pay the *New England Journal of Medicine* \$1 00 a year for each member be continued, but that any member who wished all issues of the *Journal* obtain them by sending a check for \$1 50 directly to the *Journal*.

This motion was duly seconded, and was carried.

Dr Lewin, for the Committee on Officers' Reports, then moved that Dr Metcalf's report be accepted in full.

This motion was duly seconded and was carried.

Dr Paul Dye for the Committee on Amendments to the Constitution and By-Laws, made the following recommendations to amend Article IV, Section 1, of the constitution, to read as follows: "This society shall consist of members, life members and honorary members", to amend Section III, Article 4, to read as follows: "life members shall be those members whose dues are remitted".

Dr Dye stated that these changes had been accepted unanimously by the House of Delegates in 1945 and presented in open meeting at the annual session, and should therefore come up for a final vote at the 1946 meeting.

Dr Dye also recommended that Section 1 of Chapter 10 of the by-laws be amended to read as follows: "An assessment of \$9 00 per capita on the membership of the component societies is hereby made the annual dues of this society." He pointed out that this provision meant that each county society should charge \$10 00 for its membership, retaining \$1 00 for itself and sending \$9 00 per member to the New Hampshire Medical Society, presumably, each county society would have to take similar action under its by-laws to cover these increased dues.

The Speaker stated that although this matter was presumably to be laid on the table for discussion until the following morning and although no formal action could be taken immediately, it might be wise to discuss it.

A member inquired if \$3 00 were a sufficient increase.

The Secretary stated that this increase would raise the dues enough for the coming year, and recommended such an increase, which could be raised further if great expenses were incurred.

Dr Biron recommended raising the dues to \$10 00, which would pay an assessment in toto of \$11 00.

The Speaker stated that Hillsborough County had added an assessment of \$1 00 to the dues this year,

and that every man except one had paid the \$8 00 rather than \$7 00.

The Secretary pointed out that any excess, no matter what the dues were, was turned back to the Trustees. Up to the beginning of the war, something was returned every year for the General Fund, since the beginning of war, money had been borrowed from the Trustees at the rate of \$500 to \$1000 a year.

Dr Wilkins proposed that the dues be increased to a figure that would be sufficient to support the activities of the Society, believing that if the dues were \$12 00, or anything above \$10 00, such an amount would be better than \$9 00.

The Speaker requested that all those in favor of raising the dues raise their right hands.

The decision to increase the dues was unanimous.

The Speaker then asked how many wanted the dues raised to \$9 00 or \$10 00.

Dr Montgomery inquired if there were any objection to raising the dues to \$14 00, making the total \$15 00.

The Speaker asked how much money had been withdrawn from the General Fund.

Dr Wilkins replied that \$500 had been withdrawn and that he believed that more than \$500 had been withdrawn during the previous year.

It was asked how much money was in the General Fund.

Dr Wilkins replied that there was \$4957 74 in the General Fund — a much smaller amount than had been in the Fund a few years previously because during the war the general reserve funds that had been established had been depleted to help the general running expenses of the Society.

The Speaker stated that the reserve fund could be drawn on, if necessary, whereas the other funds, like the Benevolence Fund, could not be touched.

The Secretary said that nothing had been given to the Benevolence Fund for the last three or four years.

The Speaker asked that all those in favor of \$14 00 a year raise their hands. Sixteen hands were raised. He then requested those opposed to \$14 00 per year to raise their hands. Seven hands were raised.

Dr Clough stated that on the basis of 528 members in the Society, \$2500 would be put into the General Fund, approximately \$1500 had been withdrawn in the war years, and \$2500 would be replaced. He asked for an explanation why that amount was needed in the General Fund.

Dr Lewin, as secretary of the Sullivan County Medical Society, expected to encounter some difficulty in collecting \$15 00, and believed that many of the members would greatly object.

Dr Sycamore stated that many members of the Society discharged from the armed forces might have some difficulty in meeting various extra expenses that returning to civilian life entails. He suggested that the dues might be raised sufficiently

to cover expenses for the year and that the following next year, if necessary, the dues be increased again

Dr Ladd invited attention to the fact that the \$15 00 could be deducted from income taxes, and stated that in his county the reserve fund had mounted to around \$400 or \$500

A question was asked if the General Fund were a fund to be drawn on during the war years and if there were any other functions of the fund

The Speaker replied that the Secretary had informed him that there was no other function of the General Fund, except as a reserve fund

Dr Wilkins stated that it was the General Fund that has been built up. Analysis for seven or eight years had revealed that the New Hampshire Medical Society was not self-supporting: the money received and the money paid out for various expenses required \$500 a year more from the general fund. The dues collected did not carry or cover the cost of the running of the Society, and in a year in which no money was received from the exhibitors there had been a large deficit, a similar deficit had occurred in the previous two or three years, with only a one-day meeting and with a decrease in the amount received from the exhibitors. To meet expenses, the dues of the society must be raised at least \$1 00

Dr Biron inquired whether, when the Secretary made his estimate, he considered that such a sum would not only carry the annual meeting for the next year but also perhaps repay some of the loan received from the General Fund. If so, Dr Biron believed that the estimate should be considered sufficient

The Secretary replied that he did not know exactly how much, if anything, could be paid back, but that the Society could get by on a rate of \$10 00

Dr Wilkins pointed out that the Society had always been in the position of being partially supported by the exhibitors. He believed that the Society should be able to support itself

Dr Montgomery remarked that a two-day meeting would cost more than \$1 00, and more than the \$5 00 or \$6 00 that was being asked as an increase

Dr Ladd stated that speakers from outside the State cost \$100 00 each and that expenses were high

The President expressed his opinion that the dues should be increased sufficiently to meet the expenses of the Society, but saw absolutely no reason for making the dues any higher than necessary. Until the war, the Society had always had a two-day meeting, and the reports of the Treasurer for a number of years in normal times, even on the former rate, showed that there was enough money to add a little to the General Fund, which had no specific purpose and therefore no object for being built up. The money had not been loaned with the idea that it has to be paid back. This was an emergency fund. Consequently, the President was in favor of a reasonable amount such as \$12 00, but not \$14 00, and

preferably \$10 00. The Vermont State Medical Society was said to have raised its dues to \$20 00, but that increase was necessary because a full-time executive secretary was employed

The President observed that at meetings of the House of Delegates, year after year, delegates gave a good deal of their time and consideration to particular problems that were presented to the Society. In the following year, the minutes of the previous meetings of the House of Delegates, as is customary, were always left unread. The *Transactions* of the Society were printed in the *New England Journal of Medicine*, some in one issue and some in following issues, and as a rule were not read by most members. He believed that if the minutes of the meetings could be read, much of the discussion would be unnecessary. He added that some committee of the Society could profitably make a search through the minutes of the House of Delegates for the last six years, because the time saved and duplication avoided would tend to give a progressive structure to the deliberations of the House of Delegates

The Speaker stated that the minutes of the previous meeting occupied about forty-five pages of the *Transactions* and would take about two hours to be read

The President said that if a member or a committee could bring to the House of Delegates a summary of the actions taken, and a report of whether the will of the Society had been carried out, the whole procedure would be much improved

Dr Dyé stated that a small addition to the Secretary's estimate of \$9 00 would probably ensure sufficient funds for the operation of the Society. He therefore moved that the annual dues of the Society be raised to \$10 00

This motion was duly seconded by Dr Dinerman, and on a showing of hands, the opinion was unanimous, although no official vote was taken

Dr Dye then announced that he would submit the vote for the amendment at the meeting on the following morning

Dr Lewin, in the absence of the chairman, read the report of the Committee on Child Health, as follows

The Committee on Child Health has been relatively inactive. A most important step toward the betterment of the health of the children of New Hampshire is the study of child-health services of the American Academy of Pediatrics, which is now in progress. We urge the co-operation of all the members of the Society in this study

COLIN C STEWART, *Chairman*
B READ LEWIN
FRANKLIN ROGERS

Dr Lewin moved that this report of the Committee on Child Health be accepted

This motion was duly seconded

The President stated that a physician from Massachusetts engaged in work of a similar nature to that reported would present a résumé on the child-

The Speaker asked for the opinion of those who wanted a two-day meeting. There was a unanimous showing of hands. He then stated that the motion before the House was that the next meeting of the Society should be held at the Hotel Wentworth in Portsmouth, and that if that site were not available, the President, together with the Vice-President and the Secretary, would select the site. The motion was carried.

Dr. Lewin, for the Committee on Officers' Reports, moved that the present arrangement, namely, that the Society pay the *New England Journal of Medicine* \$1.00 a year for each member be continued, but that any member who wished all issues of the *Journal* obtain them by sending a check for \$1.50 directly to the *Journal*.

This motion was duly seconded, and was carried.

Dr. Lewin, for the Committee on Officers' Reports, then moved that Dr. Metcalf's report be accepted in full.

This motion was duly seconded and was carried.

Dr. Paul Dye for the Committee on Amendments to the Constitution and By-Laws, made the following recommendations to amend Article IV, Section 1, of the constitution, to read as follows: "This society shall consist of members, life members and honorary members", to amend Section III, Article 4, to read as follows: "life members shall be those members whose dues are remitted."

Dr. Dye stated that these changes had been accepted unanimously by the House of Delegates in 1945 and presented in open meeting at the annual session, and should therefore come up for a final vote at the 1946 meeting.

Dr. Dye also recommended that Section 1 of Chapter 10 of the by-laws be amended to read as follows: "An assessment of \$9.00 per capita on the membership of the component societies is hereby made the annual dues of this society." He pointed out that this provision meant that each county society should charge \$10.00 for its membership, retaining \$1.00 for itself and sending \$9.00 per member to the New Hampshire Medical Society, presumably, each county society would have to take similar action under its by-laws to cover these increased dues.

The Speaker stated that although this matter was presumably to be laid on the table for discussion until the following morning and although no formal action could be taken immediately, it might be wise to discuss it.

A member inquired if \$3.00 were a sufficient increase.

The Secretary stated that this increase would raise the dues enough for the coming year, and recommended such an increase, which could be raised further if great expenses were incurred.

Dr. Biron recommended raising the dues to \$10.00, which would pay an assessment in toto of \$11.00.

The Speaker stated that Hillsborough County had added an assessment of \$1.00 to the dues this year,

and that every man except one had paid the \$8.00 rather than \$7.00.

The Secretary pointed out that any excess, no matter what the dues were, was turned back to the Trustees. Up to the beginning of the war, something was returned every year for the General Fund, since the beginning of war, money had been borrowed from the Trustees at the rate of \$500 to \$1000 a year.

Dr. Wilkins proposed that the dues be increased to a figure that would be sufficient to support the activities of the Society, believing that if the dues were \$12.00, or anything above \$10.00, such an amount would be better than \$9.00.

The Speaker requested that all those in favor of raising the dues raise their right hands.

The decision to increase the dues was unanimous.

The Speaker then asked how many wanted the dues raised to \$9.00 or \$10.00.

Dr. Montgomery inquired if there were any objection to raising the dues to \$14.00, making the total \$15.00.

The Speaker asked how much money had been withdrawn from the General Fund.

Dr. Wilkins replied that \$500 had been withdrawn and that he believed that more than \$500 had been withdrawn during the previous year.

It was asked how much money was in the General Fund.

Dr. Wilkins replied that there was \$4957.74 in the General Fund — a much smaller amount than had been in the Fund a few years previously because during the war the general reserve funds that had been established had been depleted to help the general running expenses of the Society.

The Speaker stated that the reserve fund could be drawn on, if necessary, whereas the other funds, like the Benevolence Fund, could not be touched.

The Secretary said that nothing had been given to the Benevolence Fund for the last three or four years.

The Speaker asked that all those in favor of \$14.00 a year raise their hands. Sixteen hands were raised. He then requested those opposed to \$14.00 per year to raise their hands. Seven hands were raised.

Dr. Clough stated that on the basis of 528 members in the Society, \$2500 would be put into the General Fund, approximately \$1500 had been withdrawn in the war years, and \$2500 would be replaced. He asked for an explanation why that amount was needed in the General Fund.

Dr. Lewin, as secretary of the Sullivan County Medical Society, expected to encounter some difficulty in collecting \$15.00, and believed that many of the members would greatly object.

Dr. Sycamore stated that many members of the Society discharged from the armed forces might have some difficulty in meeting various extra expenses that returning to civilian life entails. He suggested that the dues might be raised sufficiently

ternal deaths was 16, with a slight decrease in the birth rate as compared with the previous year. There were 8551 births in 1945.

In the tabulations to follow, it is interesting that although most cases are classified as unavoidable, a greater number of cases were regarded as having received inadequate treatment than in previous years. Of the 16 deaths, the method of delivery reported for 8 of the cases was operative or "forced." The committee cannot stress too often the opinion that there is never any justification for an *accouchement force*.

In the twelve years during which this study has been conducted, the high point was reached in 1935, with a rate of 6.1 per 1000 live births, with 46 deaths. At this point it was easy to speculate that improved obstetrics, increased knowledge, better facilities of both hospitals and physicians and intensified programs for fostering better maternity care were responsible for a lower trend, and such factors may well have been responsible. The maternal death rate rose sharply in 1943, however, and continued to climb in 1944. These being war years, the scarcity of personnel, stresses of wartime and fewer facilities, especially in hospitals, may well have been to blame. Now that 1945 has written its page in history, it is truly encouraging to note the decrease in the maternal death rate.

The committee did not attempt to do an intensive study on infant deaths under one year, or of stillbirths, time and personnel were not available for such a study. Tabulations regarding causes of infant deaths, however, follow. Again the committee includes in this report the definition of a stillbirth that has become accepted in most states. There will always be some confusion in the reporting of stillbirths because of individual interpretations, especially since the period of gestation that must be reached before registration as a stillbirth, differs in many states.

MATERNAL DEATHS

In 1945, the period of this study, there were 16 maternal deaths. The number of live births was 8551. This gives a rate of 1.9 per 1000 live births. Since 1941, the birth rate has steadily climbed, probably because of an influx of population into defense areas and more marriages among servicemen. All deaths reported occurred in hospitals.

The following is a tabulation of maternal deaths by cause for the year 1945 as established by the committee and subdivided according to causes of death as assigned by the Division of Vital Statistics in accordance with the *International List of Causes of Death* (fifth edition).

CHIEF CAUSE ACCORDING TO INTERNATIONAL CODE	NO OF CASES
Other accidents of pregnancy and specified conditions of childbirth (including death before delivery)	6
Hemorrhage of pregnancy (including death before delivery and those of puerperium)	3
Infection during childbirth and puerperium	3
Abortions	2
Puerperal toxemia	2
Total	16
CHIEF CAUSE AS CLASSIFIED BY COMMITTEE	NO OF CASES
Puerperal emboli	4
Ruptured uterus	3
Toxemias (all types)	3
Myocardial failure	2
Nonmaternal	1
Hemorrhage of childbirth	1
Unknown (incomplete data)	2
Total	16

CAUSE OF DEATH	NO OF DEATHS AS ASSIGNED BY INTERNATIONAL CODE	NO OF DEATHS AS GROUPED BY COMMITTEE

Incomplete		2
Other accidents and specified conditions of childbirth	2	
Nonmaternal deaths		1
Abortion	1	
Total	16	16

In the 16 fatal cases 5 cesarean sections were performed. The causes of death recorded were as follows: toxemia 2, post-partum hemorrhage 1, ruptured uterus 1, and unknown 1.

In 3 other cases a forced delivery was performed, and the committee interprets such procedures as referring to an *accouchement force*. These reports reveal that almost half the deaths studied (8 cases) involved operative or forceful means of delivery, only 2 of which, in the opinion of the committee, were indicated because of either a previous section or an apparent disproportion. The committee cannot justify any cause for a forced delivery.

One case to illustrate a forced delivery occurred when the attending physician during the course of a normal labor in a twenty-three-year-old multipara observed that the fetal heart was accelerated. He became alarmed and called in a consultant. From the data obtainable on the report, it appeared that, with the cervix dilated but one fingerbreadth, the consultant performed what was recorded as a forced delivery, obtaining a stillborn child. The placenta showed some infarcts. The fact that some blood clots were observed led to a diagnosis of abruptio placenta, which was given as a cause of death. The patient went into shock following delivery and expired. The committee believes the diagnosis to be incorrect from the data, but believes that the patient died as a result of the treatment, presumably from a ruptured uterus resulting from the forced delivery. It is to be remembered that this conclusion was reached from the material at hand. Whether the membranes had ruptured previously was not known and it was not recorded whether the patient was examined after death for ruptured uterus.

It has been the usual procedure for the committee to classify these deaths further to illustrate if possible where the responsibility for maternal deaths belongs. The groups are as follows: Group 1, 2 cases in which the patient was at fault because of refusal of prenatal care, neglect and so forth (1 case of obesity and myocardial failure, and 1 of eclampsia); Group 2, 4 cases in which the obstetric treatment was apparently inadequate (3 cases of ruptured

health survey by the American Academy of Pediatrics at the general meeting on the following day

It was moved and seconded that the report of the Committee on Child Health be accepted, the motion was carried

The report of the Committee on the Control of Cancer was then presented by the chairman, Dr George C Wilkins

Last year, the House of Delegates approved a suggestion of this committee that a cancer-instruction day be offered to general practitioners of the State. During April, which is cancer-control month, such a meeting was held at Manchester. A program of thirty-minute talks on the diagnosis and treatment of eight different forms of cancer was presented by five New Hampshire surgeons and three surgeons from Boston. These talks were interesting and stimulating, but the committee received slightly less than one hundred acceptances and some of those accepting did not attend. Furthermore, the men who did attend were mostly the ones who are progressive, well informed and always attend medical meetings. The committee feels a certain amount of disappointment that there were not in attendance more rural and urban general practitioners who see few cancer cases but on whom the fate of a patient with cancer chiefly depends. Your committee intends to plan another meeting next year. The expenses of the meeting, including an excellent lunch, were borne by the Field Army of the American Cancer Society.

Since our last report, two physicians attached to the cancer clinics have taken advantage of the aid given by the Field Army for refresher courses. We hope and expect that more will take advantage of this opportunity, now that so many physicians have returned from the services.

High-school education in cancer control has greatly increased. Last year, the schools in Manchester, where the experiment was initiated, asked for its continuance. Last September, with the active co-operation of the Commissioner of Education, the instruction pamphlets and teachers' guides were offered to all the high schools of the State. At the present time, over 60 per cent of the high schools are using the instruction pamphlets in the science classes. This development has been the responsibility of the Field Army, aided by your committee.

The Cancer Commission and its fourteen clinics have continued to function smoothly. Some clinics have few patients and some have many, but it has been found that the usefulness of a clinic depends chiefly on the interest, ability and enthusiasm of its director. During the past year, 1441 patients attended the clinics, of whom 592 were new patients and 849 were making return visits. Of the new patients, 51 per cent were found to have cancer.

There is continued evidence of the need of public education in the early signs of cancer, and of the value of early treatment, especially among people of the middle and older ages. The younger generation accept it more readily, and therein lies our hope of good results from continual educational efforts.

Your committee sent three short letters to all physicians in the State. One, entitled "Breast Tumors," urged the removal of all definite tumors of the breast and cited tumors as small as 5 mm that were definitely malignant. In the presence of breast tumor one should never advise "let it alone." Another letter discussed "The Significance of a Negative Biopsy Report," and explained why and how errors could be made. It was suggested that in all questionable cases a conference between the surgeon and the pathologist is always advisable. Our last letter described the usual locations of skin cancer, the usual types found, and suggestions regarding diagnosis and treatment, particularly stressing that any new growth on the skin of a patient over forty years of age should be considered malignant until proved otherwise.

Your committee recommends increasing the Committee on the Control of Cancer to five members and asks the House of Delegates to instruct the Nominating Committee to add two names.

Your committee has expended the entire amount appropriated last year. On account of the increased cost of printing and a larger number of physicians, we request the sum of \$60.00 for next year's expenses.

GEORGE C WILKINS, Chairman
RALPH E MILLER
GEORGE F DWIGELL

Dr Lewin, for the Committee on Officers' Reports, recommended that the Committee on the Control of Cancer be increased to five members. This motion was duly seconded.

Dr Dye expressed the opinion that his committee would be in agreement that Section 11 of Chapter VIII of the by-laws be amended and that the Committee on the Control of Cancer be increased to five members, and therefore moved that this recommendation be laid on the table, to be voted on at the meeting on the following morning.

This motion was duly seconded and was carried.

Dr Lewin, for the Committee on Officers' Reports, moved that the sum of \$60.00 for the Committee on the Control of Cancer be approved. This motion was duly seconded and was carried.

Dr Lewin, for the Committee on Officers' Reports then moved that the report of the Committee on the Control of Cancer be accepted and that Dr Wilkins be commended for his unceasing efforts to improve cancer diagnosis and treatment throughout the State. This motion was duly seconded and was carried.

The report of the Committee on Maternity and Infancy was then read, as follows:

Each year the Committee on Maternity and Infancy of the New Hampshire Medical Society conducts a study on the maternal deaths, infant deaths and stillbirths reported for the calendar year previously ended. This study is for mortality reported for the year 1945. As in the past, the committee has endeavored to obtain as full data as possible on each death, analyze, and so far as possible appraise and come to conclusions on the material submitted by physicians in their answers to questionnaires. It should always be borne in mind that infallible judgment is impossible and that conclusions drawn are to be interpreted in the light of objective observers looking into a situation after the event has passed and, in retrospect, appraising the conduct entering into the final result. The committee wishes to stress the fact that conclusions drawn are accurate only to the degree that data at hand are complete. Sometimes the information on a given case is scanty indeed and it is urged that physicians and hospitals make a special effort to submit information as complete as possible.

It is planned that another year the committee will submit a more complete questionnaire designed to secure as full data as possible. It is hoped that such a device will aid greatly in making the study more complete.

The information for the study was gathered from the records of physicians and hospitals. All but one physician responded to the questionnaires, most cases having been reported with fair completeness. Assistance in gathering and compiling data was obtained through personnel of the State Department of Health, and as in the past the committee did not know the identity of the physician, patient or hospital when evaluating the facts presented by their agent.

The year 1945 was gratifying in that the maternal death rate decreased from that of the two previous years. The lowest rate was in 1942 1.6 per 1000 live births. The rate in 1945 was 1.9 per 1000 live births. The number of ma-

program would be inefficient and ineffective, as well as detrimental to the best interests of patients. If government participation on the economic side of medical care is necessary through the establishment of any form of compulsory insurance, we favor the utilization of existing non-profit insurance programs under the sponsorship of medical societies, government funds being used only to pay the premiums for the insured persons. The President is discussing this problem with the county societies throughout the year, and has actively registered his opposition to the Wagner-Murray-Dingell Bill through communication with the appropriate members of Congress and government officials.

New Hampshire Physicians' Service

Gratifying progress in growth has been made throughout the last year. There are now 36,000 participants in the Surgical Division, of whom 6000 are also covered under the Medical Division. This represents a fourfold increase over the enrollment a year ago.

Financially, the Corporation has accumulated sufficient reserves to permit the repayment of the original capital loan and the extension of coverage under both the surgical and medical contracts, with a reduction of the premium for the medical contract.

Studies are now being made on the coverage of veterans care under a contract with the Veterans Bureau — a program already in effect in some other states — and on the coverage of indigent cases under a contract with the State Board of Public Welfare. Such coverage would materially increase the usefulness of the Service and would provide a valuable example of the possibility of co-operation in medical care between the government and the medical profession, with the control of the medical aspects remaining in the hands of the medical profession.

The whole-hearted co-operation of the members of the New Hampshire Medical Society in most areas of the State has been the key factor in the success of the Blue Shield program. Seventy-five per cent of the members are enrolled as participating physicians, the county enrollments running from 48 per cent to 98 per cent, seven counties have over 80 per cent enrollment. We need, however, the co-operation of the other 25 per cent to make the service fully effective. It is interesting to note that men returning from the armed forces are rapidly signing up as participating physicians. Constructive criticism has been helpful and has been gratefully accepted by the trustees of the New Hampshire Physicians' Service. Your committee wishes to commend the members of the New Hampshire Medical Society for their co-operation.

National Physicians' Committee

The National Physicians' Committee has organized a vigorous campaign against the Wagner-Murray-Dingell Bill, which undoubtedly has had considerable effect in arousing opposition throughout the nation. For this reason, the majority of your committee urges the New Hampshire Medical Society collectively and individually to support the National Physicians' Committee by encouragement and by financial aid.

The chairman is compelled to render a minority report in opposition to the methods employed, believing that the dogmatic propaganda broadcast by the National Physicians' Committee, employing on occasion apparently deliberate distortion and misrepresentation, will in the long run do a distinct disservice to the medical profession by cheapening the cause of medicine and by alienating the sympathies of the thoughtful layman.

Blue Triangle

The proposal of the New Hampshire Bankers' Association for physician-secured loans to patients for the payment of their medical bills was referred to the committee by the last House of Delegates. Your committee believes it is inadvisable to sponsor this proposal inasmuch as the Blue Triangle emblem of the plan would cause confusion with the Blue Shield and Blue Cross, and the plan itself to a certain degree would work at cross purposes with the voluntary insurance program.

L. K. SYCAMORE, *Chairman*
FRANCIS J. C. DUKE
R. W. ROBINSON

Dr Lewin, for the Committee on Officers' Reports, stated that a new and interesting approach to government participation in medical care had been brought out by the Committee on Medical Economics. If the Government must participate in medical care, it should do so only to the extent of paying the premiums for the insured persons in some prepayment-insurance program under the sponsorship of medical societies. This would be good only if participation ended there. Dr Lewin asked for discussion on whether there was agreement or disagreement with the Taft Bill as presented and whether the Government would co-operate in a prepayment plan under medical society sponsorship. He moved that the Society go on record as favoring government participation in a prepayment-insurance program under medical-society sponsorship. This motion was duly seconded.

The President, who had been in some measure associated with the development of this voluntary insurance plan in New Hampshire for some years, stated that his opinions had gone through all phases. Certainly, if the Government were to participate in this program, the only proper method was the supplying of the necessary means to cover the care given patients. The voluntary plans sponsored in the various states appeared to be the best course. He feared a very dangerous attack on the whole of the relation between patient and physician that any type of insurance or any agent assuming the cost of medical care for the patient might bring about. He pointed out that a patient must be required to make some sacrifice. He considered the local, voluntary plans much better than any compulsory insurance plan administered by anything as remote as the federal government.

In a small state like New Hampshire, the problems were close enough together for members of the professional committees of Blue Shield to regard the Blue Shield as the agent of the physician, consequently there was a definite reason for protecting it, to make its insurance successful. The President recalled a discussion two years previously regarding federal participation in medicine and whether it was impossible for the Government to collect moneys by taxation or otherwise and then to use the money for voluntary plans of insurance. The Government appeared to be interested in such a scheme.

The President further pointed out that one of the major objectives of interest in the voluntary-insurance plan was to provide some way not only of taking care of the medically indigent but also of devising a fee schedule to furnish some recompense at a time when the burden was tremendous. There had been a good deal of dissatisfaction with the system of treating the indigent under that fee schedule, which had been modified once. The President had had some discussions with the State Board of Welfare during the previous year and had suggested the State pay the insurance premium for indigent care,

uterus, and 1 of post-partum hemorrhage), Group 3, 7 deaths that were apparently unavoidable (3 cases of eclampsia, and 4 of pulmonary emboli), and Group 4, 2 cases in which data were insufficient and the cause of death was therefore undetermined (1 case of postoperative pulmonary emboli, and 1 of myocardial failure).

In 1 case in Group 3 in which the cause of death was reported as post-partum hemorrhage, the committee believed that treatment was inadequate. The patient went into shock following a cesarean section, and no intravenous therapy, particularly plasma, was administered for at least forty-five minutes, although the anesthetist was aware of the patient's condition. The committee considered the cause of death to be surgical shock rather than post-partum hemorrhage, especially since there was no evidence of excessive bleeding. It was further believed that an anesthetist should take the initiative in ordering shock therapy, especially when the attending physician has his hands full with delivery or surgery.

Maternal mortality rates per 1000 live births by years were as follows: 1933, 6.3, 1934, 5.4, 1935, 6.1, 1936, 4.8, 1937, 4.3, 1938, 3.8, 1939, 3.1, 1940, 3.1, 1941, 1.9, 1942, 1.6, 1943, 2.4, 1944, 2.9, and 1945, 1.9.

The deaths by counties in 1945 were Belknap, 1, Hillsborough, 6, Strafford 5, Coos 2, Cheshire 1, and Rockingham 1.

INFANT DEATHS

The following is a list of the ten chief causes of death recorded for infants under one year of age. In 1945 there were 299 deaths from all causes — a rate of 35 per 1000 live births. In order, the causes were prematurity, congenital malformations, birth injuries, other diseases peculiar to first year of life, lobar pneumonia, pneumonia (other), accidental suffocation, diarrhea and cerebrospinal meningitis. It should be noted that the chief cause of death listed is premature birth. The Committee believes that this should not be considered a cause of death and that better and more adequate treatment and facilities for the care of premature infants should be stressed. Maintenance of body temperature and thorough nursing care, including proper feeding, is essential.

STILLBIRTHS

In 1945 200 stillbirths were reported — a rate of 23.4 per 1000 live births. The causes were varied and substantially unrevealing. Again the committee prints the accepted definition of a stillbirth, as follows: "A fetus showing no evidence of life after complete birth (no action of heart, breathing or movement of voluntary muscle), if the twentieth week of gestation has been reached, should be registered as a stillbirth." For the most part the causes of fetal death as given on death certificates are maternal conditions, with the exception of fetal deformities. Here again the classification of causes of stillbirths varies. The International Commission for Revision of the International List of Causes of Death in 1938 adopted the following classification, which is given here in outline only: stillbirth caused by disease in, or accident to, the mother, anomalies of the fetus, placenta or cord, death of the fetus from injury or other causes, and stillbirth due to other causes. In a diagnosis of causes of death, the foregoing should be kept in mind.

COMMENTS AND RECOMMENDATIONS

By way of summary and to emphasize examples of apparently poor obstetrics the committee wishes to point out the following facts and make some suggestions. It is hoped that the conduct of future deliveries may be favorably affected by constructive criticism. The cases of toxemia reported again illustrate that there is still a tendency to neglect the medical aspects of the condition by inadequate treatment. The majority of patients with toxemia reported this year were seen late in pregnancy, with symptoms of the toxemia apparent. The tendency has been to induce labor or perform a cesarean section without giving adequate medical care or preparation. The committee strongly urges the immediate treatment of toxemia by the use of magnesium sulfate in the early stages, early induction with due regard to prematurity, glucose and magnesium sulfate in severe cases and in eclampsia

complete digitalization as soon as possible, with added use of glucose and oxygen if necessary. The magnesium sulfate, glucose and digitalization should be instituted immediately, pending the decision of the method or time of delivery. It is more important that the patient be treated than to empty the uterus.

The committee wishes to make a plea for a larger number of trained and skilled anesthetists. Many unfortunate incidents can be avoided if a trained anesthetist is constantly alert for symptoms of shock and is skilled in the administration or supervision of shock therapy. Almost every year a case is cited in which the failure of the anesthetic to act quickly or adequately leads to the patient's death.

It is urged that more autopsies should be sought. Frequently the correct diagnosis can be determined, especially in cases in which the cause of death is recorded as post-partum hemorrhage or shock. Post-partum hemorrhage may be due to retained cotyledons, ruptured uterus, cervical tears, fibromas and varicosities.

If hemorrhage is suspected, immediate search for such causes should be instituted. The committee emphasizes again the necessity of proper diagnosis and immediate treatment of patients with hemorrhage or who show signs of shock immediately or soon after delivery, whether delivery was spontaneous or operative. Plasma, now available to all free of charge, should prove an invaluable means of combating shock in such cases.

It is again stated that the committee cannot find justification for a forced delivery. In cases of transverse presentation it is possible that an external cephalic version could be attempted before labor has set in, and if the membranes are intact, the patient should surely be permitted to go to full dilatation before delivery is attempted. If the membranes have ruptured, the cervix is not dilated and the uterus is dry, an internal podalic version is definitely contraindicated. A better alternative is cesarean section.

The committee wishes to comment on the value of qualified consultation in obstetrics emphasizing that the consultant's prerequisites should include ample experience in obstetrics and not merely skill in surgery.

If the committee is to make fair and helpful suggestions, based on conclusions reached in this study, it is essential that better reporting of the facts be practiced by physicians, since the committee has nothing to go on except information submitted.

The committee wishes to thank physicians and hospitals for reports completely and painstakingly filled out, as well as all physicians who co-operated in preparing this report. Acknowledgment and thanks are also expressed to the State Department of Health for its aid in compiling data and furnishing personnel.

ROBERT O. BLOOD, *Chairman*
BENJAMIN P. BURPEE
MARION FAIRFIELD

Dr. Lewin, for the Committee on Officers' Reports, commended the work of the Committee on Maternity and Infancy and moved that the report be accepted. This motion was duly seconded and was carried.

The report of the committee on Medical Economics was then presented by the Chairman, Dr. L. K. Sycamore, as follows:

For the last year, your committee has functioned mainly in the separate activities of its members, one of whom is president of the New Hampshire Medical Society, the chairman being president of the New Hampshire Physicians' Service. These activities occupied the time of the members to such an extent that any further functioning of the committee as a whole did not seem possible. Your committee has, however, considered the following subjects and presents its conclusions in this report:

Wagner-Murray-Dingell Bill

Your committee opposes the method of distribution of medical care proposed in the bill, believing that such a

program would be inefficient and ineffective, as well as detrimental to the best interests of patients. If government participation on the economic side of medical care is necessary through the establishment of any form of compulsory insurance, we favor the utilization of existing non-profit insurance programs under the sponsorship of medical societies, government funds being used only to pay the premiums for the insured persons. The President is discussing this problem with the county societies throughout the year, and has actively registered his opposition to the Wagner-Murray-Dingell Bill through communication with the appropriate members of Congress and government officials.

New Hampshire Physicians' Service

Gratifying progress in growth has been made throughout the last year. There are now 36,000 participants in the Surgical Division, of whom 6000 are also covered under the Medical Division. This represents a fourfold increase over the enrollment a year ago.

Financially, the Corporation has accumulated sufficient reserves to permit the repayment of the original capital loan and the extension of coverage under both the surgical and medical contracts, with a reduction of the premium for the medical contract.

Studies are now being made on the coverage of veterans' care under a contract with the Veterans Bureau — a program already in effect in some other states — and on the coverage of indigent cases under a contract with the State Board of Public Welfare. Such coverage would materially increase the usefulness of the Service and would provide a valuable example of the possibility of co-operation in medical care between the government and the medical profession, with the control of the medical aspects remaining in the hands of the medical profession.

The whole-hearted co-operation of the members of the New Hampshire Medical Society in most areas of the State has been the key factor in the success of the Blue Shield program. Seventy-five per cent of the members are enrolled as participating physicians, the county enrollments running from 48 per cent to 98 per cent, seven counties have over 80 per cent enrollment. We need, however, the co-operation of the other 25 per cent to make the service fully effective. It is interesting to note that men returning from the armed forces are rapidly signing up as participating physicians. Constructive criticism has been helpful and has been gratefully accepted by the trustees of the New Hampshire Physicians' Service. Your committee wishes to commend the members of the New Hampshire Medical Society for their co-operation.

National Physicians' Committee

The National Physicians' Committee has organized a vigorous campaign against the Wagner-Murray-Dingell Bill, which undoubtedly has had considerable effect in arousing opposition throughout the nation. For this reason the majority of your committee urges the New Hampshire Medical Society collectively and individually to support the National Physicians' Committee by encouragement and by financial aid.

The chairman is compelled to render a minority report in opposition to the methods employed, believing that the dogmatic propaganda broadcast by the National Physicians' Committee, employing on occasion apparently deliberate distortion and misrepresentation, will in the long run do a distinct disservice to the medical profession by cheapening the cause of medicine and by alienating the sympathies of the thoughtful layman.

Blue Triangle

The proposal of the New Hampshire Bankers' Association for physician-secured loans to patients for the payment of their medical bills was referred to the committee by the last House of Delegates. Your committee believes it is inadvisable to sponsor this proposal inasmuch as the Blue Triangle emblem of the plan would cause confusion with the Blue Shield and Blue Cross, and the plan itself to a certain degree would work at cross purposes with the voluntary insurance program.

L. K. SYCAMORE, Chairman
FRANCIS J. C. DUBE
R. W. ROBINSON

Dr Lewin, for the Committee on Officers' Reports, stated that a new and interesting approach to government participation in medical care had been brought out by the Committee on Medical Economics. If the Government must participate in medical care, it should do so only to the extent of paying the premiums for the insured persons in some prepayment-insurance program under the sponsorship of medical societies. This would be good only if participation ended there. Dr Lewin asked for discussion on whether there was agreement or disagreement with the Taft Bill as presented and whether the Government would co-operate in a prepayment plan under medical society sponsorship. He moved that the Society go on record as favoring government participation in a prepayment-insurance program under medical-society sponsorship. This motion was duly seconded.

The President, who had been in some measure associated with the development of this voluntary insurance plan in New Hampshire for some years, stated that his opinions had gone through all phases. Certainly, if the Government were to participate in this program, the only proper method was the supplying of the necessary means to cover the care given patients. The voluntary plans sponsored in the various states appeared to be the best course. He feared a very dangerous attack on the whole of the relation between patient and physician that any type of insurance or any agent assuming the cost of medical care for the patient might bring about. He pointed out that a patient must be required to make some sacrifice. He considered the local, voluntary plans much better than any compulsory insurance plan administered by anything as remote as the federal government.

In a small state like New Hampshire, the problems were close enough together for members of the professional committees of Blue Shield to regard the Blue Shield as the agent of the physician, consequently there was a definite reason for protecting it, to make its insurance successful. The President recalled a discussion two years previously regarding federal participation in medicine and whether it was impossible for the Government to collect moneys by taxation or otherwise and then to use the money for voluntary plans of insurance. The Government appeared to be interested in such a scheme.

The President further pointed out that one of the major objectives of interest in the voluntary-insurance plan was to provide some way not only of taking care of the medically indigent but also of devising a fee schedule to furnish some recompense at a time when the burden was tremendous. There had been a good deal of dissatisfaction with the system of treating the indigent under that fee schedule, which had been modified once. The President had had some discussions with the State Board of Welfare during the previous year and had suggested the State pay the insurance premium for indigent care,

at that time the President had stated that this presented simply one attitude. The medical profession had apparently agreed that this fee schedule was better than nothing, and that it was adequate recompense for the services rendered, provided that the State paid for the care. He pointed out, however, that physicians were selling their services to the State, for the care of the indigent, for a sum considerably less than the actual worth of those services, and that physicians must protect themselves and their ideals. There was no reason for the medical profession to give its service at a moderate fee, or at a cost lower than that of the grocer or other people dispensing commodities paid for by the State. Of course, laboratory and similar fees had not been included in the insurance plan, but it had been thought that such fees could be adjusted in the insurance scheme by accepting a type of service policy, including a complete service, the fees of the physician being kept on a detailed record form.

The President further stated that every case did not agree with Dr. Sycamore's minority report condemning the National Physicians' Committee.

Dr. Wilkins objected to the suggestion that the Society approved government participation in health insurance.

Dr. Lewin accepted the objection as an amendment.

The Secretary stated that in anticipation of this discussion he had sent a telegram to the American Medical Association asking its attitude on such pro-

posals as the Taft Bill, and that the American Medical Association had replied that such proposals had not yet been considered officially. The Secretary questioned whether the House of Delegates should make any decision until the policy of the American Medical Association was known.

Dr. Clough agreed that decision on the program should be postponed, pending the opinion of the American Medical Association. Since the Blue Shield had been created to combat any interference by the Government in the practice of medicine in New Hampshire, Dr. Clough believed that it would be wiser to say nothing for the present but to consider the matter at greater length.

Dr. Ladd stated that if the motion were passed as read, the sponsors of the Wagner-Murray-Dingell Bill would at once say that the State of New Hampshire favored their bill. He therefore agreed that the wisest course was not to take any action until the attitude of the American Medical Association had been determined. He moved that the motion be laid on the table. This motion was duly seconded and was carried.

Dr. Lewin, for the Committee on Officers' Reports, moved that the House of Delegates not sponsor the Blue Triangle Plan of the New Hampshire Bankers' Association. This motion was duly seconded and was carried.

Dr. Lewin, for the Committee on Officers' Reports, then moved that the report of the Committee on Medical Economics be accepted. This motion was duly seconded and was carried.

CASE 32341

PRESENTATION OF CASE

A forty-seven-year-old shipping clerk entered the hospital because of chronic cough

The patient had been in apparent good health until a year before entry when he developed a non-productive cough, which he at first attributed to an upper respiratory infection but which persisted throughout the winter and became worse in the spring, with the development of some mucoid sputum. A physician prescribed pills that controlled the cough fairly well until the time of admission. The sputum had never contained blood or pus, and the patient denied any real pain, although he had some suprasternal and substernal soreness. He had noted no fever, but was told by his physician that he ran a slight temperature. Since the beginning of the illness he had lost 65 pounds, although his appetite had remained good.

Physical examination revealed a 2.5-cm rubbery, superficial lymph node in the right supraclavicular region, just beneath the edge of the platysma muscle, and several deeper nodes in the right supraclavicular region. The heart and lungs were completely normal. Examination of the abdomen was negative, and the liver edge could not be made out. The prostate was slightly enlarged.

The temperature was 99.8°F, the pulse 85, and the respirations 20. The blood pressure was 120 systolic, 80 diastolic.

Examination of the blood revealed a hemoglobin of 13 gm and a white-cell count of 9000. The urine was normal.

An x-ray film of the chest showed the left hilus to be low and surrounded by a homogeneous area of increased density, with irregular flame-like borders (Fig 1). In the lateral view the density was seen to occupy the hilar area. There were increased lung markings in the region of the left lower lobe and in the base of the left upper lobe, probably representing atelectatic areas. The right lung field was clear, except for a thin linear area of increased density, which probably represented minimal atelectasis. The diaphragm was normal in position, and both costophrenic angles were clear. The heart and upper mediastinum were not remarkable.

A biopsy of the right supraclavicular node and a bronchoscopy were performed.

DIFFERENTIAL DIAGNOSIS

DR. BRIANT L. DECKER: May we see the x-ray films?

DR. JAMES R. LINGLEY: This film shows the enlargement of the left hilus that is described in the record, and in the lower portion a lobular mass can be seen. The lateral view shows the density in the region of the hilus, which I believe definitely involves the base of the upper lobe and probably of the lower lobe. The right lung is clear except for this small area of atelectasis. There is no displacement of the heart, no mediastinal enlargement, and no fluid.

DR. DECKER: Is there any collapse in the left lower lobe?

DR. LINGLEY: I think that there is probably some collapse in both lobes.

DR. DECKER: Is there any calcification?

DR. LINGLEY: No.

DR. DECKER: Is this shadow a node?

DR. LINGLEY: No, I believe that it is the transverse process of a vertebra.

DR. DECKER: This forty-seven-year-old shipping clerk had had chronic cough for two years, with only mucoid sputum, and had lost 65 pounds. He had no real chest pain but had substernal soreness and slight fever. Enlarged lymph nodes were found in the right supraclavicular region on physical examination, and there were the x-ray findings that Dr. Lingley has pointed out. I assume that the two processes — that is, the x-ray appearance and the enlarged nodes — were related. Consequently I believe that this was some type of new growth. The two most probable diagnoses are primary bronchiogenic carcinoma and lymphoma, although I lean more strongly toward carcinoma. With lymphoma of this duration one would see a mediastinal mass and would find lymph nodes in the axillas and elsewhere. I believe that when invasion of the lung occurs with lymphoma it is fairly advanced, although it may occur early on rare occasions. The weight loss could go with either condition. If it were associated with carcinoma, I should expect more extensive carcinoma than was apparent in this case. The slight temperature could also go with either. From the x-ray appearance I believe that this lesion, which caused partial obstruction of bronchi, together with metastases, was most probably an adenocarcinoma. Small-cell carcinoma usually grows much more rapidly but it does spread by the lymphatic vessels. A year, however, is too long a duration for such a tumor. Squamous-cell or epidermoid carcinoma is directly invasive and usually does not involve the lymph nodes. Adenocarcinoma travels by the blood stream, is often found in the lymphatic vessels, and frequently produces distant metastases. It is perhaps more slowly growing than

a small-cell carcinoma I am most in favor of adenocarcinoma

Tuberculosis, which could have produced this picture, is unlikely in a person of this age. Lymph nodes and a process of this sort could occur in a young person or in an older patient, with more extensive tuberculosis.

Sarcoid is also a possibility, although I do not believe that so much weight loss would have been noted. Sarcoid is usually bilateral and symmetrical.

The various mycoses are unlikely because the patient's occupation did not expose him to the agents that cause such diseases — he was a shipping

DR MALLORY Dr Miller, will you tell us what you know about the case?

DR CARROLL MILLER I saw this man in my office before I sent him to the hospital, and at that time he brought with him x-ray films that had been taken elsewhere. The ray formation from the central hilar mass was more marked in those plates than in the ones taken in this hospital. In both supraclavicular fossae there were nodes that were fixed, firm and rather matted together, and I believed that the diagnosis was carcinoma of the lung, with metastases to the supraclavicular fossae, although we have seen few carcinomas of the lung that

FIGURE 1 Roentgenogram of Chest

clerk. He did not come from the Southwest, so that coccidioidal granuloma can probably be ruled out. In a chronic stage the other mycoses would have been more ulcerating, with lesions of the skin.

In conclusion I believe that this was most probably an adenocarcinoma, primary in the bronchus.

DR TRACY B. MALLORY Are there any other suggestions?

DR. DONALD C. KING Dr Sweet and I have just been talking it over, but we do not agree that adenocarcinoma is a likely diagnosis. If this was a carcinoma we believe that it was probably epidermoid

metastasized in a relatively early stage to that region, such cases do occur. Because of the weight loss, the time interval and the x-ray appearance my diagnosis was carcinoma. I think that the bronchoscopic findings were interesting and similarly confusing.

CLINICAL DIAGNOSIS

Carcinoma of lung

DR DECKER'S DIAGNOSIS

Primary bronchiogenic adenocarcinoma

ANATOMICAL DIAGNOSIS

Tuberculosis of bronchus

PATHOLOGICAL DISCUSSION

DR MALLORY On bronchoscopic examination a tumorlike outcropping was seen on the bronchial wall. The bronchoscopist also considered the appearance characteristic of carcinoma. The surprise came in the microscopic examination. The biopsy from the bronchus showed tuberculous granulation tissue, and that of the supraclavicular lymph node also showed frank caseous tuberculosis. The patient is now in a sanatorium.

CASE 32342

PRESENTATION OF CASE

A thirty-one-year-old housewife entered the hospital because of lower abdominal pain.

The patient had apparently been in good health until six weeks before entry, when she experienced crampy lower abdominal pains associated with the menstrual period. The pains were dull and aching and radiated to both sides of the lower back. The period had begun at the usual time, but bleeding was scanty and prolonged over ten days. The periods usually occurred every twenty-eight days, lasted four or five days and required about four pads. They were never accompanied by discomfort. After this period had ended, the patient continued to suffer from intermittent attacks of similar pain. The following period came at the expected time but lasted only two days, with scanty flow. Four days before entry, about an hour after supper, the pain became markedly worse, and the patient vomited her supper. The pain continued during the night, and she vomited several more times, producing whitish "phlegm and water." Her condition remained essentially unchanged, and she continued to vomit, despite taking only fluids by mouth. Two days before entry she felt somewhat improved, vomiting only once and taking some solid food. On the day of admission, however, the pain was severer than at any previous time and she again began to vomit. At no time did the vomitus contain bile, blood or coffee-ground material. She had had no bowel movement and little or no flatus during the four days before entry. Since the onset of the illness she had had sharp lower midline abdominal pain during urination, but passage of the urine itself caused no burning and the urine was not bloody. She had felt feverish during the illness but had had no chills. During the week before entry she had had a "slight cold," with rhinitis and some coughing.

The patient had four children aged twelve, ten, six and four years. Seven years previously she had had a miscarriage, and since the birth of her young-

est child she had noticed a scant whitish discharge. Both the patient and her husband denied any venereal infection.

Physical examination revealed a well developed woman who appeared acutely ill. The heart and lungs were normal. The abdomen was distended, with diminished peristalsis and some fullness in the suprapubic region. There was diffuse and rebound tenderness, most marked in the lower abdomen, especially in the midline. Pelvic examination showed a grapefruit-sized tender mass in the left vault lying laterally and anteriorly. There was no tenderness on moving the cervix.

The temperature was 99°F, the pulse 105, and the respirations 20. The blood pressure was 120 systolic, 70 diastolic.

Examination of the blood revealed a red-cell count of 2,620,000, with 7.7 gm of hemoglobin, and a white-cell count of 8900, with 74 per cent neutrophils. The corrected sedimentation rate was 66 mm per hour. The chloride was 101 milliequiv per liter, and the total protein 6.2 gm and the non-protein nitrogen 18 mg per 100 cc. A blood Hinton test was negative. The urine was normal.

A plain film of the abdomen showed only a considerable amount of gas and fecal material retained in the colon, as well as gas in what appeared to be several loops of small intestine. The pelvis was filled by a homogeneous mass of increased density that was consistent with a full bladder.

Cultures of the cervix were negative for gonococci.

On the evening of the first hospital day the temperature rose to 99.8°F, and the patient was placed on sulfadiazine and penicillin. On this regime the mass felt by vaginal examination seemed to be decreasing in size and was definitely confined to the broad ligament. The subjective symptoms also subsided until the sixteenth hospital day, when the pain in both lower quadrants returned. On the twenty-first hospital day a peritoneoscopy revealed a questionable cyst of the right ovary. On the twenty-sixth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR JOHN B. MCKITTRICK This thirty-one-year-old mother of four children, previously in excellent health, entered the hospital with the complaint of lower abdominal pains of six weeks' duration. The pains which were first noted in association with a menstrual period, were dull and aching and radiated to both sides of the lower back. The period had started in a perfectly normal fashion except that bleeding was scanty and prolonged for ten days, this was distinctly unusual, since the patient had never had discomfort with her periods and the menses had usually lasted four or five days. The amount of flow was abnormal, as were the duration and, of course, the pain. When the actual menstrual flow had ceased, the pain continued in an intermittent fashion but apparently did not change in

character. The next period came at the proper interval but was abnormal in that it lasted only two days and the flow was again scanty. This second menstrual period apparently occurred about two weeks before admission to the hospital. Four days before admission, shortly after supper, the pain became much severer and more protracted and was accompanied by repeated vomiting throughout the night of food recently eaten. Two days later the patient improved somewhat. The vomiting was less persistent, and she was able to take a small amount of solid food. On the day of admission, however, there was a sharp recrudescence of the pain and vomiting also returned, at all times the vomitus was free of blood and bile. During this four-day period, during which the symptoms had altered and become severer, a new element was introduced, namely, absence of bowel movements associated with the passage of little or no flatus. Another symptomatic clue is that during the course of the illness the patient had sharp discomfort on urination, but the passage of urine was not associated with burning and the urine was apparently normal. The patient stated that she had had no chills during the course of her illness but at times had felt feverish.

It seems clear that some acute process was going on and was localized to the abdomen and associated with the genital system. What could have caused such an abrupt change in the menstrual cycle, associated with low abdominal pain radiating through to the back and with involvement of the intestinal tract in a way that interfered with intestinal motility? Several things come to mind. Was this an inflammatory process? The patient felt feverish but had no chills. Beyond that there is no indication of how prostrated she had been by the illness. It is perfectly conceivable that pelvic inflammatory disease could persist for six weeks, becoming acute, involving the intestinal tract, — usually the small bowel, — and causing intestinal obstruction. As a rule, however, such patients are rather acutely ill, with a high fever, they frequently have chills, and when the process is as acute as this seemed to be, there is usually associated urinary symptomatology. Acute appendicitis, which frequently causes this type of abdominal pain and low-grade fever, must be considered. A patient may present such a history of several weeks' duration and may consult a physician only when symptoms become much severer as in the case under discussion. Was this a benign tumor, such as an ovarian cyst, that during a period of six weeks was intermittently and finally irreducibly twisted and caused the acute symptomatology for the last four days before admission? Such a tumor is rather unlikely, although most of the symptoms could be explained on that basis. As a rule, ovarian cysts do not cause the disturbance in the menstrual cycle that occurred in this case. They cause nausea and vomiting, as well as the type of pain that the patient complained of,

but not usually the degree of disturbance in intestinal motility that was apparently present. I think that one need mention malignant tumor only to be complete, but there was no evidence that this process was anything but acute. By a process of rapid elimination one arrives at the diagnosis that seems to fit this whole problem best — namely, some type of extrauterine pregnancy which could account for the change in the menstrual history, as well as the pain and the intestinal symptoms.

On admission to the hospital the patient was well developed and acutely ill. Physical findings were limited to the abdomen, which was distended. There were diminished peristalsis and suprapubic fullness. Diffuse tenderness and rebound tenderness were most marked in the lower abdomen, near the midline. Pelvic examination showed a grapefruit-sized tender mass lying to the left and anteriorly. There was no tenderness on moving the cervix. The temperature was 99°F, the pulse 105, and the respirations 20. The blood pressure, I am interested to note, was normal. Examination of the blood showed a red-cell count of 2,600,000, with a hemoglobin of 7.7 gm, and a normal white-cell count, with 74 per cent neutrophils, the corrected sedimentation rate was 66 mm per hour. Other studies, including the chloride, protein and nonprotein nitrogen levels and the blood Hinton reaction, were negative. Examination of the urine was also negative. A plain film of the abdomen confirmed the clinical impression of an excessive amount of retained gas and fecal material in both the large and the small bowel — primarily the former — and in addition revealed the mass palpated by the examiner, which was interpreted as being consistent with a full bladder. Apparently there were no characteristic features about this mass, but that is not surprising. Cultures of the cervix were negative for gonococci. The record does not give a vital bit of information that I am sure was determined: the results of the test for pregnancy. I do not see how one could examine this patient and listen to her history without considering that question.

In summary, this patient was acutely ill, with a mass in the pelvis, an altered menstrual cycle, and evidence of intestinal dysfunction but little suggestion of an acute inflammatory process — certainly not an inflammatory process that was causing much of a systemic reaction. The temperature was only slightly elevated, and the white-cell count was normal, although there was an elevated sedimentation rate, the upper limit of normal in this hospital being 20 mm. Just what does that mean? It is perfectly true that in some cases the sedimentation rate is elevated out of proportion to other evidences of inflammation, such as the temperature and the white-cell count, in the presence of venereal infection in the pelvic organs, and it is entirely possible that this patient had such an infection despite the negative culture and the absence of other symptoms.

usually associated with acute pelvic inflammatory disease. The sedimentation rate, however, cannot be depended on to differentiate pelvic inflammatory disease and acute appendicitis. I have mentioned acute appendicitis, and I cannot completely exclude it as the cause of the trouble. The degree of ileus I say "ileus" rather than obstruction because the distribution of the gas shadows was mostly in the large bowel, and at any rate there was certainly no small-bowel obstruction) is entirely consistent with an appendiceal abscess, as were the pain and vomiting. The unusual position of the mass — on the left and anteriorly — and the change in menstrual rhythm are strong evidence against appendiceal abscess. The presence of pelvic inflammatory disease might also account for what I believe to have been an extrauterine pregnancy. Pathologic changes that occur in the tubes following inflammatory disease predispose a patient to such difficulties. On the basis of the way the patient was handled in the hospital, I assume that the condition was considered to be acute pelvic inflammatory disease with probably a tubo-ovarian abscess, since she was treated conservatively until the twenty-sixth hospital day, when she was operated on, the negative culture from the cervix does not exclude pelvic inflammatory disease. If the diagnosis had been extrauterine pregnancy, operation would probably have been performed somewhat earlier. Despite the delay in operation, however, I believe that extrauterine pregnancy offers the best explanation for the anemia, the mass, the ileus, the absence of symptoms referable purely to infection and the change in menstrual cycle. I also believe that the pregnancy was not tubal but abdominal, possibly either ovarian or located in the broad ligament itself. I exclude tubal pregnancy because it does not, as a rule, persist for such a long time without causing dramatic symptoms when there is rupture and enough bleeding to lower the hemoglobin to 7.7 gm. Apparently the process in this patient had bled, but the bleeding was not sufficiently acute or severe to produce shock, which is almost certain to follow when the tubal pregnancy reaches the stage of rupture into the preperitoneal

cavity. She may have had an element of inflammatory disease, which I think was secondary.

My diagnosis, therefore, is extrauterine pregnancy, probably abdominal, with or without low-grade pelvic inflammatory disease.

CLINICAL DIAGNOSES

Ovarian cyst

Pelvic inflammatory disease?

DR. MCKITTRICK'S DIAGNOSIS

Extrauterine pregnancy, probably abdominal

ANATOMICAL DIAGNOSIS

Abdominal pregnancy

PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY. There was only one omission, an unintentional one, from this patient's history. She had had her appendix removed at the age of eighteen. If Dr. McKittrick had known this, one confusing factor would have been eliminated. No Aschheim-Zondek test was ever done, and if the diagnosis of pregnancy was seriously considered, such an impression was not recorded. Opinion first favored pelvic inflammatory disease and then shifted to ovarian cyst. The patient was eventually explored, with the latter as the preoperative diagnosis.

At operation a moderate amount of free blood was encountered when the peritoneal cavity was opened. A large mass was found in the left side of the pelvis posterior to the broad ligament and covered by adherent omentum. When the omental adhesions were freed a cavity was broken into, out of which a fetus measuring 9 cm. in length was extruded. A well developed placenta was adherent to the fimbria of the left fallopian tube. There was considerable old clotted blood in the posterior cul-de-sac. A left salpingectomy was done as the simplest method of dealing with the placental implantation. The pregnancy, however, was definitely extratubal and intra-abdominal, as Dr. McKittrick predicted.

GRADUATES OF NONAPPROVED MEDICAL SCHOOLS

A LETTER published elsewhere in this issue of the *Journal* calls attention again to the difficulties that graduates of nonapproved schools who served as medical officers during the war are having in obtaining additional medical training, particularly as residents in the hospitals of the Veterans Administration. Any unprejudiced discussion of the problem should be based on facts rather than on assumptions, and it seems necessary to question some of the statements contained in the letter.

In the first place, although the majority of graduates of nonapproved schools may have "really felt the 'call' to medicine," most of them were undoubtedly refused admission to approved schools because

of a premedical training that was judged to be relatively inadequate. This, combined with a medical education that failed to provide facilities comparable with those available in approved schools, places a severe handicap on such graduates, which is the obvious reason why so many of them fail to pass board examinations in the states whose statutes permit them to apply for licensure.

Secondly, state medical examining boards are not "closely regulated and governed by the American Medical Association" each state has its own medical practice act. Nor are the specialty boards "by products" of the American Medical Association. The American Board of Surgery, for example, arose following initial efforts by the American Surgical Association, being finally created by the Advisory Board of Medical Specialties after the field had been approved by the Council on Medical Education and Hospitals of the American Medical Association. This board has thirteen members, only three of whom represent the American Medical Association.

Thirdly, it should be emphasized that practically all graduates of nonapproved schools who recently served as medical officers came from two states, — Illinois and Massachusetts, — since these are the only states that regularly permit such graduates to apply for licensure.

When all is said and done, the problems of the graduates of nonapproved schools practically limit themselves to Illinois and Massachusetts, and at least in the latter, efforts are being made to provide these men with further opportunities. All such graduates are eligible to apply for membership in the Massachusetts Medical Society five years after they have been licensed to practice. The Gallupe Plan, commented on editorially in the April 25 issue of the *Journal*, offers to these men hospital affiliation, it is sponsored by the Massachusetts Medical Society and the Massachusetts Hospital Association and has the approval of the Council on Medical Education and Hospitals of the American Medical Association and of the American College of Surgeons. Finally during the past year the Massachusetts Medical Society has conducted courses of postgraduate medical instruction throughout the Commonwealth that have been open to all physicians. It is true that in Massachusetts there is a distinction between the

raduates of approved and nonapproved schools, on the other hand, the proper authorities appear to be doing all that they can to help the latter in improving their medical training

In any discussion concerning the appointment of graduates of nonapproved medical schools as residents in hospitals of the Veterans Administration, it is essential to differentiate two types of institutions — "hospitals" and "affiliated hospitals." The former are solely under the control of the Veterans Administration, and graduates of nonapproved schools have been accepted as residents in these hospitals. The latter, on the other hand, are run in connection with various medical schools and are in the process of being converted into teaching hospitals for those who are desirous of qualifying for certification by one of the specialty boards. The selection of residents is subject to the approval of a committee representing the affiliated medical school or schools, — the Dean's Committee in Massachusetts — and an attempt is made to select only those men who seem likeliest to pass the examinations of their respective specialty boards on the termination of their training. Many graduates of approved schools in the United States and Canada have been turned down, but at least in Massachusetts, some men who do not so qualify have been accepted. Although existing regulations bar the latter from certification by the majority of specialty boards, there is no doubt that the Dean's Committee will do its utmost to make their certification possible, provided that they creditably complete their residencies.

Although the path of the graduates of nonapproved schools is not easy, it appears that those who have shown industry, professional skill and a desire to better themselves have more opportunities now than ever before.

SELF-DEMAND IN INFANT FEEDING

AN ANCIENT fact has been rediscovered as a new theory in infant feeding and, being put to the test, has again been proved, namely, that babies who are fed when they are hungry are in the main happier than babies who are put to nurse when they are not hungry and are denied nourishment when they ask for it. We are witnessing now, in these matters,

a pleasant swing from a gravely pontifical attitude toward the training of the very young to a rather indulgent point of view, admitting that babies are human beings like, for instance, ourselves.

We may be sure that this so-called "self-demand regime" is a relative innovation only among the more cultured classes and that many babies less fortunately situated in other ways have had certain vital needs attended to more promptly, even if in a less determinedly organized fashion. This particular swing away from the regimentation of infancy that accompanied the birth of the specialty pediatrics was initiated, or at least blessed, by that ardent student of infant behavior, Arnold Gesell.

As early as 1937, Gesell and Ilg¹ expressed themselves on this point as follows:

Superficially it might appear that the self-demand schedule would encourage whims and instability in the child. Exactly the opposite is true. For by individualization of feeding the infant is most directly and most completely satisfied. He is satisfied vegetatively and emotionally. He escapes periods of want, anxiety and distress. The promptness and the certainty of satisfaction cumulatively experienced . . . will nourish that sense of security which is essential to mental health.

Other experimenters in this naturalistic method of feeding babies when they are hungry and not forcing them to eat at other times are presenting the results of their own explorations. Notable among these, Trainham, Pilafian and Kraft,² one of the authors being the mother, allowed a pair of lusty, breast-fed twins to write their own tickets for thirteen long months. The results were eminently satisfactory to the infants, although the mother, at times, found herself producing and serving as many as ten meals in a day. This, however, was an unusual case.

On the whole we must accept the obvious conclusion that the inflexibility of a mathematical attitude has been allowed to prevail much too far in the care of an extremely unmathematical subject. We have fallen into the error of believing that fixed quantities of food of prescribed caloric value must be absorbed by infants of certain weights and ages at regular intervals and in a stated number of minutes. Far better is it that more babies, at least during the early weeks of their infancy, should be allowed to benefit from the examples set by these articulate observers and the host of more humble infant guardians who always fed by the baby rather

than by the clock After a few days or a few weeks, in most cases, the baby can be led — not forced — to accept a schedule more in accordance with that which his parents would like to follow

DEATHS

HUBER — Edward G Huber, M.D., of Wahan, died July 23 He was in his sixty-fifth year

Dr Huber was born in Menomonie, Wisconsin graduated from the University of Michigan in 1903 and received his medical degree from its medical school in 1905 After a short period of private practice in Missouri, he entered the Army Medical School, graduating in 1908 Following service in the Philippines, he was sent to France during World War I and was in command of a hospital center While assigned to the First Corps Area, he attended and graduated from the Harvard School of Public Health in 1923 He retired from the Army in 1935 with the rank of colonel, and then accepted a position in the Massachusetts Department of Public Health, as well as an instructorship in the Harvard School of Public Health He was appointed acting dean of the latter in 1942 and was made associate dean and professor of public health at the time of the recent organization of the school, in which he took an extremely active part He was a member of the American College of Physicians and a fellow of the American Medical Association

His widow and a daughter survive

KINNEY — William D Kinney, M.D., of Osterville, died July 12 He was in his seventy-fourth year

Dr Kinney received his degree from Bowdoin Medical School in 1899 and had practiced in Osterville for nearly half a century He had been associate medical examiner of Barnstable County for twenty years and had always been active in the affairs of the Massachusetts Medical Society, having been a member of the Council and a supervising censor for many years, as well as president of his district society from 1913 to 1915

His widow and a son survive

STACEY — Charles F Stacey, M.D., of Blue Hill, Maine (formerly of Boston), died July 18 He was in his eightieth year

Dr Stacey received his degree from Harvard Medical School in 1892 He was a member of the Massachusetts Medical Society and a fellow of the American Medical Association

His widow survives

NEW HAMPSHIRE MEDICAL SOCIETY

DEATH

CLAGGETT — Fred P Claggett, M.D., of Newport, died July 4 He was in his seventy-eighth year

Dr Claggett received his degree from Dartmouth Medical School in 1897 He was a former president of the Sullivan County Medical Society and a fellow of the American Medical Association

A son and two daughters survive

MEDICOLEGAL ABSTRACT

Relation of Patient and Physician Liability for malpractice. A recent decision of the Supreme Judicial Court of Massachusetts contains several points of interest to the medical profession The action concerned a claim for so negligently treating a throat ailment as to cause the plaintiff's intestate to die

On November 24, 1941, the intestate was suffering from a severe cold Two days later he complained of a sore throat He did not respond to tablets and a gargle prescribed by a physician other than the defendant On November 27 he was admitted to a hospital conducted by the defendant On November 28 the patient's wife, who had worked as a practical nurse for ten years, saw him, he was very ill and cold, complained of pain in his sides, and was coughing On November 29, when his wife again saw him, his face was flushed and he was coughing up brownish sputum She told the floor nurse that he had pneumonia In stating the case the court said

If a person has a cough, a previous history of a cold and a pain in his sides, and complains of being cold, the defendant would be suspicious that pneumonia had started, and if on the next day he discovered a definite dullness on percussion of the chest, an increase in the voice sounds, bronchial or harsh breathing sounds, a flushing of the face, a high temperature and the common symptom of a rusty colored sputum containing dark-brown blood, a definite diagnosis of pneumonia could then be made A hospital record, in the handwriting of the defendant, stated that the lungs of the intestate were clear on November 27, 1941, and on November 30, 1941 According to this record, the intestate on November 30, 1941, was objecting rather violently to treatment and to taking nourishment The defendant called upon the welfare authorities to remove the intestate from the hospital On the afternoon of November 30, 1941, he was driven in an automobile by a police officer sixty to seventy miles to the Tewksbury State Hospital An examination at this hospital on the morning of December 1, 1941, disclosed that there was "bronchovesicular breathing at the left base with coarse rales throughout" The examining physician suspected that the intestate had pneumonia The intestate died on the evening of December 1, 1941

It was undisputed that the intestate was suffering from Vincent's angina when he was admitted to the defendant's hospital This disease starts with a laceration of the pharynx in the region of the tonsils, and as it progresses involves the entire mucous coating of the mouth The temperature and pulse are increased and the patient becomes very ill There may be chills and the sputum becomes rusty colored

The defendant apparently admitted that it would be improper practice for an X—— doctor to remove a patient from X—— to Tewksbury knowing that he had pneumonia, since such removal might use up his strength and cause his death An expert testified that if a patient had Vincent's angina and if it was known that he also had pneumonia, it was bad medical practice for the defendant to order his removal from X—— to Tewksbury The court was of the opinion that the question was proper, because there was evidence that the defendant should have known that the intestate had

pneumonia Where this evidence came from is not clear from the opinion.

After the expert testified as above, further examination revealed that he was not familiar with X—— practice Subsequently he was asked whether it was proper practice for a physician in a town the size of X—— to permit a man with a temperature of 100°F to be moved some sixty miles Although the layman might suppose that any well qualified doctor could answer such a question, it has long been an established rule of law that the standard of care required of a doctor depends on the standards of the particular community in which he practices, and since the witness admitted lack of knowledge concerning X—— practice, the trial judge could not properly allow him to answer this question when it was objected to by the defense

The jury found for the plaintiff, and the court was of the opinion that the evidence was sufficient to warrant such a finding

The plaintiff's declaration was for death caused by the negligent treatment of a sore throat. The evidence was such that the jury could believe that death was caused by the improper removal of the intestate from X—— to Tewksbury Ordinarily a physician may discontinue treatment of a patient without incurring liability, if his treatment, up to the time of discontinuance, has been proper In this case the physician was liable because the manner in which he discontinued the treatment was in itself the cause of injury to the patient — 1946 Adv Sh 945, July 8, 1946

CORRESPONDENCE

CHIGGERS IN MASSACHUSETTS

To the Editor This brief report I believe is justified, since it has generally been assumed that New England is free from chigger, the six-legged larva of the mite *Trombicula alfreddugesi*, otherwise known as harvest mite or red bug

I recently saw a family of four who had always lived in the heart of New York City but who had lately bought an abandoned estate in Plymouth They all had had cases of poison ivy, but they also presented a rash, especially on the legs, which to my mind was typical of chigger infestation, since I had had a chance one summer to see a large number of cases in North Carolina and Tennessee As it was night, it was impossible to look for the causative insect, but the following morning the family captured some and sent them to me, preserved in toilet water There was no question whatever about their identity, but to be absolutely sure, I sent them to Dr Howard J Parkhurst, of Toledo, Ohio, who is unquestionably this country's expert on chigger He kindly identified them for me

There also appears to be a focus of infestation in Hyannis, although I have so far been unable to capture any of the insects

Chigger infestation is of common occurrence throughout the South and up through the central states to the Great Lakes, but it has been supposed to stop in its northeastward distribution somewhere in Pennsylvania and New Jersey

GRADUATES OF NONAPPROVED MEDICAL SCHOOLS

To the Editor In concurring with Dr John D Lane's letter in the June 13 issue of the *Journal*, I should like to take this opportunity to elaborate further on the subject of discrimination against medical graduates of nonapproved schools

The majority of these men who have knowingly attended unapproved schools did so because they really felt the "call" to medicine There was no family desire for a doctor nor the glory of being called a "doctor" The love for the profession of their calling and their desire to help their fellow man drove them on to acquire the necessary knowledge This drive had to be very strong in order to overcome the obstacles thrown in their path by the American Medical Association's rules and regulations As a result they received more out of their education in medicine because they had to put more into it to compete with graduates of approved schools

Many graduates of unapproved schools entered the various branches of the armed forces during the past emergency as medical officers, and in every way competed on equal footing with other medical officers They were equally exposed to the same dangers, hardships, injuries and death as medical officers of approved schools and in many instances were decorated for bravery for extraordinary performance of duty Therefore it came as a great surprise to the writer that on inquiring from the Department of Medicine and Surgery of the Veterans Administration he was informed that even though graduates of unapproved medical schools are considered veterans, and were considered to have the necessary education and ability to treat the boys during the war and on the battlefields, now they are not considered capable of being assigned as residents in the veterans' hospitals In other words, the American Medical Association and its by-products, namely the specialty boards, will not permit graduates of unapproved schools who served as medical officers in one of the branches of the armed forces to be appointed as residents They have by this means prevented these men from further learning and training, which would allow them to treat their fellow man with the best possible knowledge and methods available

I have repeatedly sent letters to the Department of Medicine and Surgery of the Veterans Administration on this point, and they pass the buck on to the specialty boards — in my case the American Board of Surgery In corresponding with the secretary of this board my question "whether or not a veterans' hospital would lose its residency status if it appointed veterans of World War II who are graduates of an unapproved school as residents" is repeatedly and completely ignored Therefore, it appears to me that if the Veterans Administration is passing the buck, and in so doing preventing graduates of unapproved schools from keeping up with new methods and treatments in their field of endeavor, it is showing once again the obstacles put before these men by the mighty powers of the American Medical Association

It should also be called to the attention of those in power that the restrictions of hospital privileges and the right to practice their profession in whatever state they so desire are a definite form of discrimination These privileges should be allowed to all graduates of legally chartered medical schools who have passed the examinations given to graduates of approved schools and who have served an approved internship The refusal of allowing these privileges is fully as undemocratic as under a dictatorship The rules of the various state medical examining boards are closely regulated and governed by the American Medical Association

I should like to close with the final statement, which I believe hits the nail on the head "A school never made a man — a man makes a school"

BOOK REVIEWS

Your Hair and Its Care By Oscar L. Levin, M.D., and Howard T. Behrman, M.D. 12^o, cloth, 184 pp. New York: Emerson Books, Incorporated, 1945. \$2.00.

This book, written for the lay reader, does not contain too much scientific material. The style is clear and concise, and the advice contained is quite sensible. It is a book that can be read with profit and enjoyment by both physician and patient. The final chapter, entitled "Questions and Answers," gives an excellent condensed summary of recent scientific knowledge concerning the anatomy, physiology, pathology and proper care of the scalp.

Bone-Grafting in the Treatment of Fractures By J. R. Armstrong, M.D., M.Ch., F.R.C.S. With a foreword by R. Watson-Jones, B.Sc., M.Ch. Orth., F.R.C.S. 8^o, cloth, 175 pp., with 204 illustrations. Baltimore: Williams and Wilkins Company, 1945. \$7.00.

This well written and effectively illustrated book should find a ready welcome among those who treat a large number of fractures. Methods of bone grafting are described for fractures of the spine and of the upper and lower extremity; the author usually prefers an onlay graft obtained from the tibia, which is fixed in place with nonoxidizing metal screws. Prolonged immobilization in plaster accompanied and followed by reconditioning exercises is advocated. For these procedures the no-touch technic is practiced. For the most part the author follows the usual indications for operative treatment of fractures, but in his enthusiasm he advocates its use much earlier in many cases than would be considered wise in American clinics.

A foreword by Sir Reginald Watson-Jones gives a timely warning concerning infection. Although bone grafting as the author describes it is a most valuable aid in the treatment of a number of difficult fractures, it is a matter not to be undertaken lightly, for infection is worse than nonunion or malalignment.

Penicillin and Other Antibiotic Agents By Wallace E. Herrell, M.D., M.S. 8^o, cloth, 348 pp., with 45 illustrations and 45 tables. Philadelphia: W. B. Saunders Company, 1945. \$5.00.

Publications of the Mayo Clinic bear unmistakable hallmarks: almost invariably they are well printed and clearly illustrated, are written in simple, understandable style, include a good bibliography, and are accurately and comprehensively indexed. This volume is typical of such publications.

The subject matter is divided into four parts of approximately the same length. The first part gives an admirable account of the development of penicillin, describes its method of preparation, its physical and chemical properties, how it behaves in contact with bacteria, how it is standardized, and how its concentration in body fluids can best be measured. The second and third parts are clinical. The reader unfamiliar with penicillin will find these pages of particular interest. The conditions in which the use of penicillin is indicated are well described, as is its proper method of administration and dosage. The illustrations help to make the text more interesting and more easily understood. The fourth part discusses other antibiotic agents—tyrothricin, streptothricin, streptomycin and similar substances—and brings out the far-reaching developments in medical research that the work of Dubos with gramicidin and of Fleming with penicillin has already stimulated.

Not many years ago the science of pharmacology appeared to be sluggish; chemotherapy and the discovery of antibiotics have opened an entirely new chapter in medical history, which is being studied with astonishing diligence. This book tells the whole story in an engaging fashion. It is a readable, informative and useful contribution.

NOTICES

ANNOUNCEMENT

Dr. Virgil G. Casten, having returned from over five years of naval service, has resumed the practice of ophthalmology at 412 Beacon Street, Boston.

AMERICAN DIABETES ASSOCIATION

The American Diabetes Association will hold its sixth annual session on September 16 to 18, 1946 in Toronto, Canada. The first day of the meeting will be devoted to celebrating the twenty-fifth anniversary of the discovery of insulin. The program has been arranged by the University of Toronto and will feature distinguished guests from government and medical circles. Among the latter will be Drs. C. H. Best and W. R. Campbell from Canada, Drs. E. P. Joslin, R. M. Wilder, Seale Harris, David P. Barr, and Eugene Op from the United States, Dr. R. D. Lawrence from England, Dr. H. C. Hagedorn from Denmark and Dr. B. A. Housay from Argentina. On the second day, the program has as its theme a review of the accomplishments of the past twenty-five years in various aspects of diabetes. Papers will be presented on diet, insulin, coma, gangrene, pregnancy and longevity. The third day will be divided into two sessions. The morning will consist of a presentation of experimental work and research in various phases of insulin and diabetes. The afternoon session will feature a series of short papers on recent investigations in the complications of diabetes. This will be followed by an open forum presided over by Dr. R. M. Wilder, incoming president of the American Diabetes Association. There will be a board of experts who will answer questions from the floor, in a "Stump the Experts" quiz program.

This elaborate program promises to be a fitting tribute to the memory of Dr. Frederick Banting.

CONGRESS ON INDUSTRIAL HEALTH

The schedule of events for the seventh annual Congress on Industrial Health, which is to be held at the Copley-Plaza Hotel, Boston, September 30 through October 2, is as follows:

Monday, September 30

Clinical Toxicological Conference	All day
Topic — "Lead Poisoning"	
Surgical Conference	
Topic — "The Foot in Industry"	Afternoon
Professional Relations Conference and Dinner	Evening

Tuesday, October 1

General Session	Morning
Topic — "Human Relations in Industry"	
Elective Seminars	Afternoon
Section A — Industrial Physiology	
Section B — Administrative Methods	
Section C — Workmen's Compensation	
Dinner and Conference on Pan-American Industrial Health	Evening

Wednesday, October 2

General Session	Morning
Topic — "Atomic Energy: Its effects in industry and medicine"	Afternoon
General Session	Afternoon
Topic — "A Positive Health Program for Industry"	
Dinner and Conference on Health and Welfare Programs in Industry	Evening

NEW ENGLAND HOSPITAL
FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, September 5, in the classroom of the Nurses' Residence at 7:15 p.m. Dr. Felicia A. Banas will discuss mesenteric thrombosis, and Dr. Wyland F. Leadbetter, genitourinary tuberculosis. Dr. Grace E. Rochford will be chairman.

THE TREATMENT OF SUBACUTE BACTERIAL ENDOCARDITIS WITH PENICILLIN IN PEANUT OIL AND BEESWAX*

ARTHUR J. GEIGER, M.D.,† AND JESSAMINE R. GOERNER, M.D.‡

NEW HAVEN, CONNECTICUT

THE apparent curability of subacute bacterial endocarditis with penicillin has been unequivocally established within the last two years.¹ The essentials of successful therapeutics consist of treatment with massive daily doses of penicillin for a month or longer, the actual amount given daily depending on the resistance of the infecting organism to penicillin and on the serum penicillin concentrations attained. Supplementation of the penicillin with heparin, as first advocated by Loewe and his associates,² has proved unnecessary in our experience³ as well as that of others,¹ and the dispensability of this costly and usually troublesome adjuvant has gratifyingly simplified the therapeutic regimen. The necessity for prolonged and uninterrupted parenteral treatment in this disease, however, has imposed a considerable task on the professional attendants and has demanded no small measure of fortitude from the patients, who must either submit to intramuscular injections at hourly or two-hourly intervals night and day or tolerate continuous intravenous or intramuscular infusion for weeks and sometimes for months. These difficulties and objections could be largely eliminated if satisfactory and sustained serum penicillin levels were attainable, either with oral medication or by the infrequent injection of massive deposits of penicillin in a slowly absorbable form.

ORAL ADMINISTRATION OF PENICILLIN

The considerable destruction of penicillin in the stomach and the ready absorbability of certain drugs from the sublingual mucous membrane led to a preliminary trial of penicillin by this route in 3 patients. Penicillin was administered in small triturated tablets in 50,000-unit amounts, but no penicillin was detected in blood samples taken at half-hour intervals during the next five hours.

The ingestion of penicillin tablets, solutions or suspensions, with or without antacid buffering and

adsorbing agents, is already well known to yield appreciable amounts of penicillin in the blood.⁴ For the treatment of subacute bacterial endocarditis, however, this form of medication cannot yet be considered feasible — first because oral doses must be at least several times as large as parenteral doses to achieve comparable serum concentrations, which makes the cost of prolonged treatment prohibitively high, and second because it is necessary to repeat oral medication at about two-hour intervals night and day to maintain effective serum concentrations, and this is obviously objectionable when treatment must be carried on for weeks and months. For these reasons the treatment of subacute bacterial endocarditis with penicillin given orally has not been considered feasible thus far.

PARENTERAL DEPOSITS OF PENICILLIN IN SLOWLY ABSORBABLE FORM

Romansky⁵ has recently developed a slowly absorbable preparation of penicillin for parenteral use by suspending the drug in a mixture of peanut oil and beeswax, and he has demonstrated that ample and prolonged concentrations of penicillin in the blood serum follow single injections of 1 cc. or more of a mixture containing 300,000 units per cubic centimeter.⁶ Moreover, the therapeutic efficacy of this preparation in the cure of large numbers of cases of gonorrhea and syphilis given one injection daily has already been conclusively established.^{7, 8}

During the past year we had a unique opportunity to compare the effect of penicillin in oil and beeswax with that of water-soluble penicillin in the treatment of a patient with subacute bacterial endocarditis who, although refractory to cure, could be kept asymptomatic, afebrile and with sterile blood cultures so long as he received at least 250,000 units of penicillin parenterally each day, either in two-hourly intramuscular injections or by continuous intravenous drip. If a similar therapeutic remission could be maintained indefinitely with a single daily injection of penicillin in oil and beeswax, continued hospitalization would no longer be necessary, and

‡Fellow in internal medicine, Yale University School of Medicine.

the patient might be able to survive without symptoms and with no more restriction or inconvenience than that imposed on a diabetic patient taking insulin. This result was achieved in the case that follows.

CASE 1 V. H., a 45-year-old engineer, in June, 1944, developed symptoms and signs of subacute bacterial endocarditis on a background of rheumatic heart disease with mitral and aortic valvular lesions. The infecting organism, *Streptococcus viridans*, proved inhibitable in vitro by penicillin concentrations of 0.04 units per cubic centimeter of culture. Treatment for 10 months with water-soluble penicillin in daily doses ranging from 240,000 to 600,000 units and administered either in fractionated intramuscular injections

been interrupted for 3 weeks, an Osler's node appeared on one finger, without other developments except bacteremia.

The demonstration in this case that single daily injections of penicillin in oil and beeswax could maintain clinical remission and sterility of the blood just as effectively as had been previously accomplished with parenterally administered water-soluble penicillin encouraged us to try this form of therapy in the next case.

CASE 2 A. B., a 59-year-old housewife, had been ill for 5 months with fatigue, anorexia, periodic fever and night sweats. During this period she lost 35 pounds in weight. The

FIGURE 1 Case 2

at two-hour intervals or by continuous intravenous drip was regularly attended by clinical remission and sterilization of the blood. Whenever treatment was interrupted to evaluate the clinical status, however, *Str. viridans* promptly reappeared in the blood. The extraction of an infected tooth and removal of the spleen, which were suspected as foci of reinfection, did not alter the course. The infecting organism did not change its resistance to penicillin in vitro during this long period. Although this 10-month treatment failed to cure the patient, it was apparent that he could be kept clinically well and with sterile blood so long as penicillin was regularly furnished.

Following a few test injections of penicillin in oil and beeswax in June, 1945, sustained treatment with this preparation* was begun in July and was continued until December 14. The injections, which were given intramuscularly, consisted of 300,000 to 450,000 units of penicillin, given either once daily or on alternate days in doses of 600,000 units. Treatment was periodically interrupted for brief intervals to evaluate the clinical status.

During the periods of daily treatment the patient remained afebrile and clinically asymptomatic, and the blood cultures were consistently sterile. The 600,000-unit doses at two-day intervals were abandoned after a month's trial because bacteremia was not consistently suppressed by this regimen. The patient gained several pounds in weight, gradually resumed an approximately normal level of activity and received permission to return to his work during the fall. That he was not cured, however, was apparent from the regular return of bacteremia within 2 weeks of any interruption in therapy. The patient kept a daily chart of his afternoon temperature for 6 months after his discharge, and throughout this period he remained afebrile. On one occasion, when treatment had

past history included erythema nodosum in 1938, acute appendicitis in 1942 and typhoid fever at the age of 6, when, the patient asserted, a heart murmur was noted.

Physical examination disclosed an appearance of chronic illness but no wasting of the body. The heart, which was moderately enlarged, presented a harsh and moderately loud systolic murmur over the entire precordium, together with a faint systolic thrill at the apex. The liver edge was barely palpable, but the spleen was not felt. The finger ends were slightly club-shaped, and a fading petechia was noted over the left malleolus. There was a moderate hypochromic anemia with a white-cell count of 15,000 cells, 85 per cent of which were neutrophils. The blood was negative serologically, the urine was normal, and an electrocardiogram was normal. Roentgenograms of the chest showed moderate enlargement of the left auricle and ventricle. Four cultures of the blood revealed *Str. viridans* (two colonies per cubic centimeter) and the organism proved inhibitable by 0.02 units of penicillin per cubic centimeter of culture.

During the first 5 days, the rectal temperature reached 101 and 102°F, but within 24 hours of the commencement of penicillin therapy it fell below 100°F, and it remained there through most of the ensuing 6 weeks in the hospital. Following the preliminary administration of regular penicillin in doses of 20,000 units intramuscularly at 2-hour intervals for 6 days, treatment was changed to a single daily intramuscular deposit of 1.5 cc. (450,000 units) of penicillin in oil and beeswax, and the injections were continued for 19 days longer. Cultures of the blood continued sterile throughout the period of treatment no petechiae appeared, and the appetite and strength soon returned. At about the midpoint of the penicillin course, slight clouding of vision on the right developed accompanied by slight edema in the region of the macula and continued for several days. Shortly before discharge an unruptured and a devitalized tooth were extracted, and penicil-

*The material was supplied for experimental use in this case through the courtesy of Dr. Charles Church of E. R. Squibb & Sons, New York City.

lin and sulfadiazine were given prophylactically for 2 days following the operation. The clinical course and laboratory data are illustrated in Figure 1. One week after discharge, generalized urticaria developed for several days.

Since termination of the formal course of treatment on November 16, 1945, the patient has continued entirely well and without congestive failure. She has gained 16 pounds in weight, and all of fifteen blood cultures have been sterile.

The apparently successful outcome in this patient treated almost entirely with penicillin in oil and beeswax led us to treat the next case with this preparation alone.

CASE 3. M W, a 40-year-old housewife, had had rheumatic fever at the age of 20 and was known to have had a heart murmur since then. In December, 1945, she developed insidious fever, drenching sweats and amenorrhea and lost 7 pounds in weight. Her physician noted several petechiae in the 2nd week of illness, and a blood culture made at that time yielded *Str. viridans*. Treatment with penicillin was begun promptly at another hospital, and the patient received 210,000 units daily for 25 days intramuscularly, in doses of 35,000 units every 4 or 5 hours. Although fever and symptoms subsided during the period of treatment, the patient relapsed both clinically and bacteriologically within a week of the termination of therapy. She entered the New Haven Hospital for further treatment on February 18, 1946.

The abnormal findings on admission included a temperature of 102.6°F, an Osler's node on a fingertip, two subungual hemorrhages and a petechia on an eyelid and another on the right breast. The spleen was barely palpable. The heart, which was moderately enlarged, presented a loud, harsh and long apical systolic murmur with wide transmission. The heart sounds were otherwise normal, and there was no congestive failure.

A moderate anemia without leukocytosis was present. Four successive blood cultures were positive for *Str. viridans* (10 colonies per cubic centimeter), and the organism proved inhibitable by 0.02 units of penicillin per cubic centimeter in vitro.

Treatment consisted entirely of intramuscular deposits of penicillin in oil and beeswax. Because a single injection of 1 cc (300,000 units) was found to yield serum penicillin concentrations of 0.16 units per cubic centimeter at the end of 12 hours and less than 0.04 units at the end of 24 hours, it was decided to repeat the doses at 12-hour intervals, and this was done for 30 days. Symptoms subsided within a week, no further petechiae appeared, the spleen became impalpable, and the patient gained 4 pounds in weight. Cultures of the blood were sterile throughout the period of treatment and also during a deliberate interruption of therapy for 48 hours near the end of the therapeutic course. A moderate elevation of the erythrocytic sedimentation rate and an irregular fever of about 1°F, which persisted throughout the period of treatment, was attributed to the penicillin in oil and wax, for each deposit caused considerable local pain and some swelling, with occasional local redness. The temperature became normal within 48 hours of the cessation of the injections and remained so.

The treatment was stopped on March 25. The patient has remained asymptomatic and has resumed her household activities, and nine successive cultures of the blood have been sterile. She has gained another 4 pounds in weight, and the amenorrhea, which was present for 4 months, has given way to normal menstruation.

SERUM PENICILLIN CONCENTRATIONS

Intramuscular deposition of various amounts of the penicillin in oil and beeswax mixture in 5 patients yielded serum penicillin concentrations through forty-eight-hour periods, as shown in Table 1. Reasonably adequate levels were usually noted for twelve hours, and appreciable amounts of penicillin were often still present at the end of twenty-four hours. The fairly wide scattering of values at any time interval following an injection

suggests either considerable variation in the relative rates of absorption and excretion of the penicillin or deficient potency of some of the doses. Most of the material had been supplied in 10-cc vials, and it is conceivable that the reheating of such vials for

injections of 1 cc may have reduced potency. On the other hand, from his much larger experience, the material is relatively heat-stable.

DISCUSSION

In the absence of previous reports of patients receiving penicillin in oil and beeswax for several weeks to months, observations regarding local and general untoward effects from such injections are of interest. The patient in Case 1 suffered only minimal local discomfort from the daily injections, practically all of which were given into the lateral aspects of the thighs. Slight local swelling was sometimes apparent for a few days, but even after six months of almost daily deposits there was no apparent local induration or lumpiness. It is also of interest that although this patient had a history of hay fever with occasional mild asthma, no allergic manifestations, either local or general, made their appearance in spite of several interruptions of the therapeutic course. The patients in Cases 2 and 3 suffered considerable local swelling and soreness, sometimes with erythema, which lasted for several days following each injection. The buttocks proved definitely preferable to other sites for the injections in these cases. In Case 2, a week following the last injection profuse urticaria developed for the first time in the patient's life. Five months later skin patch and scratch tests with penicillin, peanut oil and the penicillin-oil-wax mixture were performed, with negative results. Two slightly tender subcutaneous nodules, probably attributable to the previous therapy, were noted in the buttocks at that time.

In the beginning the handling and injection of the semisolid mixture proved extremely troublesome and difficult. Observance of the following technical details eliminated all difficulties. The ampule of material was kept at room temperature for a few

hours before use — it may be stored at room temperature — and was heated in water at 45°C for several minutes to melt the material and render it injectable. The needles and syringe, which must be scrupulously dry, were also warmed to prevent cooling and congealing of the material during the injection. The warmed mixture, when flowing freely in the tilted vial, was quickly withdrawn through a 15-gauge needle into a 2-cc or 3-cc syringe with a snugly fitting piston, the air seal could be improved by applying a drop of sterile mineral oil to the distal half of the piston. The injection was made without delay through a 20-gauge needle. Lastly, more effective injection force was applied by the use of a syringe whose barrel was equipped with a pair of finger grippers.*

The attainability of considerable concentrations of penicillin in the serum for prolonged periods following single injections of penicillin in a mixture with oil and beeswax and the demonstration of the apparent curability of subacute bacterial endocarditis with this preparation given once or twice daily for several weeks offer a therapeutic regimen far simpler for both the patient and the professional attendants than any previously employed in the treatment of this disease. The question naturally arises whether, with this form of penicillin, patients may be treated at home and spared the long and costly hospitalization hitherto required. This would admittedly be feasible provided certain minimum bacteriologic controls were not neglected. The infecting organism in every case should be isolated from the blood, identified as a species reasonably inhibitable by penicillin and tested for its sensitivity to penicillin. Finally, one should have assurance that the concentrations of penicillin attained in the blood under the conditions of the treatment generously exceed the minimal inhibition level of the organism. To treat without such bacteriologic controls is to invite defeat through either inadequate dosage or too long intervals between injections — circumstances that may occasionally lead to increased resistance of the infecting organism to penicillin. Under circumstances in which bacteriologic facilities are minimal, some measures of control of the therapy may be achieved by the following simple and abbreviated procedure. One cubic centimeter of the patient's serum, previously warmed to 56°C for five minutes to eliminate serum-inhibiting factors,⁹ is diluted with three volumes of broth media and is inoculated with an eighteen-hour blood-broth culture of the patient's organism, a tube containing 4 cc of broth only is similarly inoculated as a control for viability of the organism. Inhibition of growth in the tube containing serum implies that the penicillin concentrations are at least four times as high as the inhibition level of the organism concerned. Preliminary experiments for comparing this technic with actual measurements of the penicillin

serum levels, with a minor modification of the method of Rammelkamp,¹⁰ suggest that it is valid.

Two favorable factors probably contributed to the rapid apparent cure in 2 of our cases. In the first place, the infecting organisms proved relatively sensitive to penicillin *in vitro*. In the second place, satisfactory concentrations of penicillin were attained in the blood with either a single daily injection of 1.5 cc or a twice-daily injection of 1 cc. The coincidence of such favorable circumstances cannot be taken for granted. Recent reports of extensive studies in patients treated for venereal diseases indicate that injections of 1 cc (300,000 units) fail to maintain serum penicillin concentrations in excess of 0.10 unit for more than twelve hours in the majority of cases, and that more voluminous injections serve chiefly to raise the initial serum levels rather than to prolong the effects.^{7, 8} One may infer from this that most cases of subacute bacterial endocarditis require injections at twelve-hour intervals to assure maintenance of serum penicillin levels high enough to inhibit the majority of strains of *Streptococcus viridans*.

SUMMARY

Apparent cure in 2 cases of subacute bacterial endocarditis due to *Streptococcus viridans* was effected with one or two daily injections of massive doses of penicillin in a mixture of peanut oil and beeswax.

In another case, which had proved refractory to cure after ten months' treatment with water-soluble penicillin given parenterally, an afebrile and asymptomatic state with sterility of the blood was maintained with a single daily injection of penicillin in oil and beeswax. Positive blood cultures, however, were obtained whenever this treatment was discontinued. It is believed that this patient can be kept indefinitely in a state of remission by this simple ambulatory form of treatment.

Satisfactory serum-penicillin concentrations were present for twelve hours and often for twenty-four hours following a single injection of 300,000 to 600,000 units of penicillin in oil and beeswax.

STATISTICS OF DIABETES*

HERBERT H MARKS†

NEW YORK CITY

THE statistics of diabetes will be considered under eight headings — prevalence of diabetes, characteristics of the diabetic population, mortality from diabetes, international comparisons, trend of diabetes in wartime, significance of geographical variations in diabetes, longevity of diabetic patients and use of statistics in clinical diabetes

PREVALENCE OF DIABETES

The first consideration is the total volume of diabetes in the country. Frankly, it is not known with any degree of accuracy how many diabetic persons there are in the United States, but there is a certain body of facts on which to work. Some guidance can be gained from the annual death toll. In 1943, the last year for which statistics for the entire country are available, the number of deaths recorded as due to diabetes within the country was 36,314. At that time, there were approximately 2,500,000 Americans serving abroad in the armed forces, but the number of deaths from diabetes among them — the pick of the young men — was negligible. During the last five years, the number of deaths from diabetes has averaged nearly 35,000 per annum.

Not all deaths of diabetic persons are recorded as due to diabetes. There is a certain degree of understatement arising out of the fact that deaths of diabetic patients from such causes as cancer, tuberculosis and accidents are classified under these other causes. Thus, in 1940 in the United States, 3991 deaths were reported in which diabetes was secondary to some other cause, as compared with 35,015 in which it was the primary cause of death. The total number of persons reported as dying *with* diabetes, 39,006, was 11 per cent greater than the number recorded as dying from diabetes. In other cases, the diabetes has not been mentioned on the death certificate because the physician certifying the death did not consider that the diabetes caused it or because he did not know that the patient was diabetic. The study of Joslin and Lombard¹ indicates that the total number of deaths from diabetes may be understated by as much as 50 per cent. If one is conservative and assumes an understatement of 25 per cent, this means that the number of persons dying annually *with* diabetes is of the order of 45,000.

A rough approximation of the total number of diabetic persons may be made from the total number of deaths, together with such facts as are at

hand on the longevity of these persons. The latest figures from the George F. Baker Clinic give the average duration of diabetes from onset to death as twelve years. Crude estimates based on life-table analyses of the mortality among patients of the clinic yield a somewhat higher figure — between fifteen and twenty years. These figures, however, are probably significantly higher than would be found true for the population as a whole. For example, a study in Philadelphia² showed a duration of only seven and five-tenths years. There are probably no more than 15 living diabetic persons per diabetic death. Applied to the reported number of deaths from diabetes, this would yield a figure of 525,000, applied to the estimate of persons dying *with* diabetes, it would yield one of 675,000.

The other sources of information on the number of diabetic persons are various surveys of the population. Three such sources will be discussed — the National Health Survey of 1935–1936 and the studies among selectees in Boston and in New Orleans.

The National Health Survey, conducted during the winter of 1935–1936 under the auspices of the United States Public Health Service, covered approximately 2,500,000 persons living in seven hundred thousand households in eighty-three cities. It was so planned as to constitute a representative sample of the general urban population of the country. Some rural families were canvassed but were excluded in the final analysis of data. The facts on disease as reported by members of households were recorded by trained enumerators. Wherever possible, an effort was made to confirm these statements through attending physicians. Among the families surveyed, 9182 cases of diabetes were reported, a total equivalent to 3.5 per 1000 population.³ When the rates by sex and age were applied to the country as a whole as of the date of the survey, the resulting estimate of diabetic persons in the country was 450,000. Certain further adjustments of the figures, however, were made by the statisticians of the Public Health Service. The report of the National Health Survey contained an estimate of 660,000 diabetic persons in the country as of 1937.⁴ Applying the prevalence rates by sex and age to the 1940 population yields a total of 500,000 diabetic persons in that year, and if the same adjustment were applied to this figure as was done in the 1937 estimate, the total in 1940 would be 725,000.

With regard to the National Health Survey, there are certain points to be emphasized. First, the survey estimate was based on the urban population covered. As will be seen, available statistics show

*From the Statistical Bureau, Metropolitan Life Insurance Company. A lecture given in the Postgraduate Course on Diabetes, Harvard Medical School, October 1, 1945.

†Manager, Insurance Medical Statistics, Metropolitan Life Insurance Company; chairman, Committee on Statistical Investigation, American Diabetes Association.

that, age being considered, the prevalence of diabetes is higher in the city than in the country. Hence, on these grounds, estimates for the country as a whole, based on the National Health Survey, would tend to be high. On the other hand, a survey such as this could not be expected to identify every case, a deficiency that is offset only in part by errors of the opposite kind — namely, the inclusion of persons reported as diabetic who were not so. It is not known which of the two factors — the use of urban data in the estimate or the unavoidable failure to include some cases in the survey — is of the greater importance. Apart from this, the method and extent of the adjustment of the basic figures of the survey that yielded the 1937 estimate of 660,000 are of doubtful validity. All in all, however, the basic unadjusted figures of the National Health Survey may be considered minimal.

Data based on Selective Service findings such as were reported by Blotner, Hyde and Kingsley⁵ are significant in that such studies cover a relatively but not wholly unselected group of males within a certain age limit. Blotner and Hyde's figures for the Boston area are extraordinarily high — so high, in fact, that for reasons that have been published elsewhere,⁶ one must be cautious about accepting them at face value. Thus, the prevalence rates in this sample, analyzed by age, were three to five times as high as in the National Health Survey. It is notable, moreover, that the number of previously known diabetic persons in the group was approximately what would be expected on the basis of the National Health Survey prevalence rates at these ages. These previously known cases constituted only one fifth of the diabetic total. Fortunately, efforts are under way to collect similar data elsewhere and to follow up the cases first diagnosed as diabetic on Selective Service examination, to see whether the diagnosis is confirmed on subsequent examination. Certainly, if the Blotner and Hyde figures are valid, this means a sharp upward revision in the estimates of the diabetic population, at least at the young adult ages.

In sharp contrast to the Boston figures are those published by Spellberg and Leff,⁷ who reported on the findings at the New Orleans Induction Station during 1944. There, among 32,000 consecutive selectees, only 37 men with glycosuria were found, and of these only 9 were diagnosed as true diabetic patients. The proportion with glycosuria was thus only 1 per 1000, as compared with 8 in Boston. The corresponding figures for diabetes were 0.3 and 4.5 per 1000, respectively. Even eliminating the older men from the Boston series, because few of the New Orleans selectees in 1944 were over thirty-five, there is still a wide gap between the two studies. Spellberg and Leff cite a number of factors that bear on the situation, but the difference is too large to be accounted for by these factors alone.

Another important point regarding estimates of prevalence of diabetes is that the diabetic population is not static, so that any set of estimates needs to be revised periodically. The population continues to increase, and at the same time there is occurring a change in its internal composition that is significant with regard to diabetes — namely, the relative increase in the population at the older ages, and more especially the female population, among whom the prevalence of diabetes is highest. Other things being equal, this brings about a more rapid increase in the diabetic population than in the general population. Still another consideration is that the increasing longevity of diabetic patients will, for some time to come, at least, widen the margin between the number of new diabetic patients discovered each year and the number of such patients dying each year. An analysis based on the prevalence figures of the National Health Survey and the mortality among diabetic patients indicates that the number of new cases of the disease is at least 50,000 a year.¹ How much higher the actual figure is, one has no way of knowing, but it may be as high as 75,000 a year. This may be matched against the figure of 35,000 deaths from diabetes and the estimate of 45,000 deaths of persons *with* diabetes. On the basis of these figures, the annual increase in the diabetic population lies somewhere between 5000 and 30,000 a year. Computations based on the prevalence rates of the National Health Survey, together with estimates of future population, indicate a net increase of 10,000 diabetic patients a year.

CHARACTERISTICS OF THE DIABETIC POPULATION

It is of interest to see how the diabetic population is constituted. The chief features of its makeup, in 1940, estimated from the prevalence rates of the National Health Survey, were as follows: 38.5 per cent of the diabetic persons were males and 61.5 per cent were females, a ratio of 10:16. In childhood and young adult life the extent and the prevalence rates of diabetes for males and females are approximately the same. Between the ages of thirty and eighty, there is a sharp sex divergence. The maximum difference in prevalence rates between the sexes is seen between forty-five and sixty-five, when the rates for females are approximately double those for males. There is some doubt whether there is any sex difference in diabetes prevalence rates in extreme old age because of the small number of observations at the later ages of life. Of course, there are many more aged diabetic women than men because at these ages women far outnumber men in the general population.

The prevalence rates in both sexes showed a steady increase with age to a maximum in the early seventies. At ages under thirty, less than 1 person per 1000 population was found to be diabetic in the

ational Health Survey In the early seventies, somewhat over 15 per cent of the male population and about 25 per cent of the female population, was found to be diabetic

MORTALITY FROM DIABETES

The latest available national data on deaths from diabetes, those for 1943, showed it to be eighth in rank among the causes of death and seventh in rank among the diseases. Among white women over forty-five years of age, diabetes was fifth in rank among the causes of death. The importance of this disease in middle-aged and older women is shown by the fact that in 1943 it caused three times as many deaths among white women older than forty-five as did tuberculosis.

The country's death rate from diabetes in 1943, based on the 36,314 deaths recorded among persons resident in the country, was 27.1 per 100,000 estimated population. This was the highest crude death rate for diabetes recorded in the United States up to the present time. It must be borne in mind, however, that the rate was artificially somewhat increased by the absence abroad of large numbers of young men and women, among whom the death rate from diabetes is particularly low, since the armed forces exclude known diabetic patients. Indications are that the crude death rate fell moderately during 1944, as well as thus far in 1945. The present year's record is comparatively favorable because of the extremely low prevalence of respiratory disease during the past winter.

The trend of the recorded death rate of diabetes in the United States has been generally upward for the entire period during which statistics of causes of death have been assembled in this country. This has held true even since insulin became available for the treatment of diabetes. The highest rates in the country's history have been recorded in recent years. Facts for the country as a whole over the years are not available. Registration of deaths in many of the states was unsatisfactory until comparatively recent years, and only since 1933 have statistics for the entire country been available. In 1900, registration was satisfactory in only ten states and the District of Columbia. These comprise what are called the "Original Registration States." Studies in long-term trends of mortality are generally best related to the findings in these states, since they differ materially from the country as a whole in the composition of their population as regards sex, race and age.

In the Original Registration States in 1900, the death rate from diabetes was 11.0 per 100,000. In 1940, the rate in the same area was 35.5, or over three times the rate in 1900. In the later year, the rate for the entire country was 26.6 per 100,000. As has been indicated, an appreciable part of the rise in the diabetes mortality is due to the increasing proportion of older persons in the population. A recent

publication of the Census Bureau³ shows that when the sex-age specific rates for earlier years are adjusted to the 1940 population, the death rate for 1900 is increased from 11.0 to 13.0 per 1000, and the increase in the diabetes rate for the Expanding Registration Area is a trifle over 100 per cent after such adjustment, as against an increase of 140 per cent in the unadjusted rate.

The effect of the change in the age composition of the population on the death rate of diabetes is further shown by the fact that the average annual increase in recorded rates between 1921 and 1940 is 1.4 per cent when allowance is made for such changes, as compared with an increase of 2.5 per cent per annum before such allowance is made.

The increase in this death rate in the last decade or so has been comparatively slight. Between 1933, when mortality data first became available for the entire country, and 1940, the death rate, adjusted to the 1940 population distribution, increased only from 24.1 to 26.6, or a trifle over 10 per cent. Statistics of the Metropolitan Life Insurance Company show that between 1931-1933 and 1941-1943 the death rate of diabetes at all ages combined, when adjusted to allow for changes in the age and sex composition of the insured population, displayed a moderate decline among white males, a very slight increase among Negro males and a slight decrease among females, both white and Negro. Similar comparisons of 1941-1943 with 1921-1923 show a moderate decline among white males but substantial increases among white females and among Negroes of both sexes. When the data are analyzed by age, however, there are found substantial decreases at every age up to fifty-five among white persons of both sexes. It is thus only among older persons that increases in diabetes death rates are found, and such increases in recent years have been relatively small. Similar data by age for the United States between 1920 and 1940, undifferentiated as regards race and sex, show sharply lowered rates among young persons. The decline extends up to the age of forty-five, whereas marked increases in the rate are closely limited to the age of sixty-five and over.

Urban death rates from diabetes, regardless of the size of the city, are considerably higher than the rates in rural areas.³ In 1940, the adjusted urban rate at all ages was over one and a half times as high as that in rural areas. In the aggregate, the rates for the cities show no marked differentials according to size of city. Such a differential does exist for females but not for males. In every group, however, the highest rate is found in the cities of 100,000 or more.

The mortality from diabetes among white persons is now little higher than that among Negroes. For both sexes combined, the white rate in 1940, adjusted for differences in the sex and age composition of the population groups, was 15 per cent above the Negro

that, age being considered, the prevalence of diabetes is higher in the city than in the country. Hence, on these grounds, estimates for the country as a whole, based on the National Health Survey, would tend to be high. On the other hand, a survey such as this could not be expected to identify every case, a deficiency that is offset only in part by errors of the opposite kind — namely, the inclusion of persons reported as diabetic who were not so. It is not known which of the two factors — the use of urban data in the estimate or the unavoidable failure to include some cases in the survey — is of the greater importance. Apart from this, the method and extent of the adjustment of the basic figures of the survey that yielded the 1937 estimate of 660,000 are of doubtful validity. All in all, however, the basic unadjusted figures of the National Health Survey may be considered minimal.

Data based on Selective Service findings such as were reported by Blotner, Hyde and Kingsley⁵ are significant in that such studies cover a relatively but not wholly unselected group of males within a certain age limit. Blotner and Hyde's figures for the Boston area are extraordinarily high — so high, in fact, that for reasons that have been published elsewhere,⁶ one must be cautious about accepting them at face value. Thus, the prevalence rates in this sample, analyzed by age, were three to five times as high as in the National Health Survey. It is notable, moreover, that the number of previously known diabetic persons in the group was approximately what would be expected on the basis of the National Health Survey prevalence rates at these ages. These previously known cases constituted only one fifth of the diabetic total. Fortunately, efforts are under way to collect similar data elsewhere and to follow up the cases first diagnosed as diabetic on Selective Service examination, to see whether the diagnosis is confirmed on subsequent examination. Certainly, if the Blotner and Hyde figures are valid, this means a sharp upward revision in the estimates of the diabetic population, at least at the young adult ages.

In sharp contrast to the Boston figures are those published by Spellberg and Leff,⁷ who reported on the findings at the New Orleans Induction Station during 1944. There, among 32,000 consecutive selectees, only 37 men with glycosuria were found, and of these only 9 were diagnosed as true diabetic patients. The proportion with glycosuria was thus only 1 per 1000, as compared with 8 in Boston. The corresponding figures for diabetes were 0.3 and 4.5 per 1000, respectively. Even eliminating the older men from the Boston series, because few of the New Orleans selectees in 1944 were over thirty-five, there is still a wide gap between the two studies. Spellberg and Leff cite a number of factors that bear on the situation, but the difference is too large to be accounted for by these factors alone.

Another important point regarding estimates of prevalence of diabetes is that the diabetic population is not static, so that any set of estimates needs to be revised periodically. The population continues to increase, and at the same time there is occurring a change in its internal composition that is significant with regard to diabetes — namely, the relative increase in the population at the older ages, and more especially the female population, among whom the prevalence of diabetes is highest. Other things being equal, this brings about a more rapid increase in the diabetic population than in the general population. Still another consideration is that the increasing longevity of diabetic patients will, for some time to come, at least, widen the margin between the number of new diabetic patients discovered each year and the number of such patients dying each year. An analysis based on the prevalence figures of the National Health Survey and the mortality among diabetic patients indicates that the number of new cases of the disease is at least 50,000 a year.¹ How much higher the actual figure is, one has no way of knowing, but it may be as high as 75,000 a year. This may be matched against the figure of 35,000 deaths from diabetes and the estimate of 45,000 deaths of persons *with* diabetes. On the basis of these figures, the annual increase in the diabetic population lies somewhere between 5000 and 30,000 a year. Computations based on the prevalence rates of the National Health Survey, together with estimates of future population, indicate a net increase of 10,000 diabetic patients a year.

CHARACTERISTICS OF THE DIABETIC POPULATION

It is of interest to see how the diabetic population is constituted. The chief features of its makeup, in 1940, estimated from the prevalence rates of the National Health Survey, were as follows: 38.5 per cent of the diabetic persons were males and 61.5 per cent were females, a ratio of 10:16. In childhood and young adult life the extent and the prevalence rates of diabetes for males and females are approximately the same. Between the ages of thirty and eighty, there is a sharp sex divergence. The maximum difference in prevalence rates between the sexes is seen between forty-five and sixty-five, when the rates for females are approximately double those for males. There is some doubt whether there is any sex difference in diabetes prevalence rates in extreme old age because of the small number of observations at the later ages of life. Of course, there are many more aged diabetic women than men because at these ages women far outnumber men in the general population.

The prevalence rates in both sexes showed a steady increase with age to a maximum in the early seventies. At ages under thirty, less than 1 person per 1000 population was found to be diabetic in the

quently reported it is least accurately reported. Search for cases of the disease will be well rewarded.

LONGEVITY OF DIABETIC PATIENTS

As against the steady increase in the diabetes death rate in the general population, there is the striking paradox that diabetic patients, particularly since the introduction of insulin, have shown steady gains in longevity¹¹ and that this has been associated with improvement in their general health and working capacity¹². The diabetic child of two generations ago could look forward to but a year or two of severely restricted life. Today, the expectation of life of the average diabetic child aged ten is estimated at forty years. Similar, though smaller, gains have been recorded among diabetic patients at other periods of life. Naturally, the gain is progressively smaller with increasing age. It is thus clear that the increase in mortality from diabetes in the general population can be explained only by a large and steady increase in the number of known diabetic patients. It is impossible in this lecture to go into the matter in detail, but the chief reasons are the increase in the proportion of older persons in the population, the more frequent discovery of diabetes as the result of improved diagnostic aids and the wider application of these measures, and certain environmental conditions that favor the onset of the disease in predisposed persons.

It is significant, furthermore, that life-table analysis of the causes of death among diabetic patients shows a reduction in the rates of death from most causes, especially those that reflect the degree of control of the diabetes.¹³ Thus, the rate of death from coma has declined progressively and rapidly. This applies likewise in a measure to tuberculosis, pneumonia and even to gangrene. The new chemotherapeutic agents promise even further reductions in many of these causes and in particular, fortunately, in diabetic gangrene. Cancer is the only important cause of death to show some increase, and this is not unexpected in view of the similar trend in the general population and the increased longevity of diabetic patients.

THE USE OF STATISTICS IN CLINICAL DIABETES

This discussion of the use of statistics in studies of diabetes is necessarily limited to certain broad considerations. Because of the rapid advances in the treatment of diabetes, and because it is a disease in which quantitative laboratory measurements are so important, there is more room and more need for statistics in clinical diabetes than in most fields of medicine. I need hardly remind this audience of the real differences of opinion that exist regarding the management of diabetes generally and of certain phases of the disease. The solution of the problems involved in these conflicting opinions can be expedited by the collection and analysis of clinical statistics by individual physicians or even by groups

of physicians following more or less the same methods. The statistical method enables the physician to substitute facts for impressions on specific matters of treatment, as well as to compare results obtained with similar findings elsewhere. When such analysis reveals significant differences, it puts the physician on the alert to ferret out the causes and to introduce such changes in methods as the facts suggest. In teaching the subject of diabetes to medical students, the statistical approach is often effective.

There is also a broad field of community service to diabetic patients in which collection and analysis of statistics is of great importance and potential benefit. I refer to the study of the causes of diabetic fatalities in the community, in which a start has been made in several places, including Philadelphia and Cincinnati. As concerns the value of medical statistical studies of this nature, one should note the remarkable reductions in maternal mortality in many cities achieved as the result of a program of study of the causes of maternal deaths and the institution of a program to correct the faults disclosed. Progress against appendicitis also has been helped by statistical studies of community experience. In like manner, comparable programs in the field of diabetes conducted in cities or urban areas throughout the country should be effective in reducing the number of deaths from diabetic coma and even of those from diabetic gangrene. The statistics are, of course, not the cure for the situation, but they afford a solid basis of fact on which programs of public and professional educational efforts can be established.

A fundamental condition of reliable statistics on diabetes in clinical practice is a set of good records. There are required an adequate general record form on the history of the patient and subsidiary forms that give sufficiently detailed facts regarding his status from time to time and the methods of treatment used in diabetic emergencies. I urge you to look over the forms used at this and other leading clinics to see that your own records contain at least the essential items of information and that these records are complete and systematic. A greater degree of standardization in record forms than has yet been achieved is desirable. Further efforts along these lines should be encouraged.

One of the greatest needs in the field of diabetes, as well as in many fields of medicine, is long-range study of results of treatment. This means adequate follow-up of large numbers of patients. A fundamental consideration in such studies is that the follow-up be as complete and thorough as it is possible to make it. A 100 per cent result is desirable but, of course, not always practicable. Nevertheless, it should be the goal. In the follow-up studies of cases at the George F. Baker Clinic, all but 1 or 2 per cent of the patients have been located. The achievement of good follow-up results is largely a

rate It is interesting to observe, however, that at most ages up to fifty-five, Negroes have appreciably higher death rates from diabetes than do Whites of the same age After fifty-five, the situation is reversed Among older people, the rates for Whites are double those for Negroes, or even more

There is a distinct difference between the sexes with regard to the relative mortality from diabetes according to color The rate for white females is only 3 per cent higher than that for Negroesses, whereas the rate for white males exceeds that for Negroes by nearly 40 per cent But as between city and country, females exhibit a notable difference according to color, the rates for Negroesses in all classes of cities being higher than those for white females, whereas in the rural areas the rates for white females are appreciably higher than those for Negroesses

There are marked regional differences in the mortality recorded from diabetes The rates are generally highest in the industrialized northeastern section of the country and lowest in the South and Southwest Differences in the rates in part reflect differences in the age makeup of the population, and when these are allowed for the gap between the highest and the lowest states is appreciably narrowed

A recent analysis of the crude or unadjusted rates shows that the increase in diabetes mortality is a country-wide phenomenon⁹ Comparison of the figures for 1940-1942 with those for 1930-1932 shows, curiously enough, that the increase has generally been most rapid in the states with the highest rates

INTERNATIONAL COMPARISONS

There is comparatively little information on the trend of diabetes abroad since the war began Consequently, any comparisons of this nature must chiefly rest on the situation before the war At that time, the United States had the highest mortality from diabetes among the nations of the world Generally speaking, the next highest death rates were recorded in certain countries of western Europe The rate in Canada is appreciably less than that in this country, but a great part of the difference between the two countries is attributable to the younger average age of the Canadian population In Europe the highest rates in prewar years were recorded in Denmark, Germany Switzerland, Holland, England and Belgium The rate in France was considerably lower, but French vital statistics are notoriously inaccurate with respect to causes of death The recorded death rates in southern and eastern Europe were extremely low This applies likewise to the few countries in Central and South America and to the few areas of the Orient for which figures are available In contrast, the white populations in the English colonies and dominions show rates that are comparable to the figures in western Europe

Prior to the war, an increase in diabetes death rates was practically a world-wide phenomenon in all the countries for which long-term records were available It is notable, however, that after the use of insulin began, there was a sharp reduction in the rates among children and young adults in practically all the countries for which statistics are available As in this country, the upward trend of the death rate at all ages combined reflected the increase in rates at the later ages of life

TREND OF DIABETES IN WARTIME

It was noted during World War I that there occurred an appreciable fall in the diabetes death rate in countries whose civilian populations were severely affected There is comparatively little information on this matter for World War II In the United States, Canada, Australia and New Zealand, the war had relatively little effect on the diabetes death rate In England, on the other hand, the death rate from diabetes fell more than 20 per cent.

SIGNIFICANCE OF GEOGRAPHICAL VARIATIONS IN DIABETES

Many factors are responsible for the great range of variation in diabetes mortality, and presumably in morbidity also, from state to state in this country and from one country to another throughout the world Particular mention has been made of such factors as the sex and age composition of populations In general, it will be found that the reported mortality and prevalence of diabetes are greatest where the highest standards of living are found and where the general level of medical care and medical practice is farthest advanced

The wide differences in the reported figures, after allowance has been made for obvious factors, are still further narrowed when a special effort is made to look for the disease The survey of diabetes made in Arizona a few years ago by the state's physicians under the guidance and inspiration of Dr Elliott P Joslin showed this admirably¹⁰ Thus, whereas only two or three deaths are reported annually from diabetes among the Indians of Arizona, the survey, which covered at most only two thirds of the Indian population of the state, disclosed 73 living Indians with the disease The estimated incidence of diabetes, based on the survey, was found to be of practically the same order as that recorded in the household canvass of 1929-1931 in Massachusetts and in the National Health Survey of 1935-1936 Moreover, the distribution of diabetes in Arizona was typical of that elsewhere there were more diabetic women than diabetic men, and more old than young diabetic persons, the rate in the small population of Jews in the state was relatively high, and morbidity rates in special groups studied were comparable to those of similar groups elsewhere It is likely, therefore, that where diabetes is least fre-

THE increasing use of Pentothal Sodium as an important anesthetic agent during major surgical procedures is well attested in the current literature on methods of anesthesia. That its optimal usefulness with the greatest measure of safety is achieved when it is employed in conjunction with supplemental anesthetic agents is borne out by reports relating to such conjoint use or by those that discuss in passing the supplemental use of other agents. My¹ previous report discussed the combined use of intravenous Pentothal Sodium and local nerve block (splanchnic) in upper abdominal surgery. In this earlier study, in which a new splanchnic needle guide was described, the two major purposes sought by the novocain nerve block were, first, to provide flaccid paralysis of the rectus abdominis muscle and second, to obliterate the visceral sensory impulses by splanchnic nerve block. By this rational supplementation of Pentothal Sodium with novocain block, a sharp reduction in the quantity of the former required for anesthesia was accomplished.

As surgical experience under Pentothal Sodium is extended, it becomes more and more apparent that one is dealing with an unusual opportunity to study accurately the precise physiologic background of surgical anesthesia in human beings. This premise turns on the evident dominance of the neurogenic reflexes initiated by surgical trauma during Pentothal Sodium anesthesia in reflexly activating the respiratory center, on the specificity of the respiratory response to the surgical reflexes arising from the segmental subdivisions of the terminal cerebrospinal nerves — cervical, thoracic, lumbar and sacral, and finally on the repressive action of Pentothal Sodium on the reflexly activated center.

The first site of pharmacologic action by Pentothal Sodium is the cerebral cortex, whereby unconsciousness supervenes, the second site appears to be the thalamus, whereby all reflex motor response to surgical trauma is controlled as a result of suppression in this relay center of all sensory impulses directed toward the cortex, the third site of action is the respiratory center, whereby, in the absence of reflex stimulation from surgical trauma, there is a completely smooth graded depression of respiratory activity. Under the conditions of a surgical operation, however, painful (noxious) stimuli of constantly varying intensity are conducted from the

field of operation over the afferent limb of intact reflex arcs to the respiratory center. Depending on whether the inspiratory or expiratory neurons are specifically activated, the afferent limbs of the arcs carry back impulses that alter the character of respiration in a specific manner. Thus, the effective administration of Pentothal Sodium as an anesthetic agent resolves itself into an effort to achieve an optimal yet safe balance between the depressing action of this drug on the reflexly activated respiratory center and the stimulating action of neurogenic stimuli impinging on it that have been initiated by trauma in the field of operation. The goal sought in effectuating this balance is that of respiratory quietude without undue depression of respiration.

The introduction of novocain nerve block in anesthesia under Pentothal Sodium is directed at strategically placing the solution so as to interrupt transfer of noxious afferent stimuli centrally, thus minimizing the reflex stimulation of the respiratory center. By such a physiologic maneuver the intermittent demands for increased administration of Pentothal Sodium are eliminated and the total overall demand for the drug is sharply reduced. My experience during the last two years with the systematic combined use of these two methods of anesthesia has sustained experimentally in human beings the following generalization made in 1945 by Gordh:² "The more the physiology of anesthesia is studied, the more strikingly becomes the predominance of the part played by respiration. Indeed the physiology of respiration may be said to dominate the physiology of anesthesia."

The present study continues the report of my experiences with the combined use of Pentothal Sodium and local nerve block as a method of anesthesia in major surgical procedures. The present report specifically discusses the use of intravenous Pentothal Sodium combined with intercostal nerve block in the performance of radical mastectomy for carcinoma of the breast. It is based on a comparative study of two groups of cases. The first group consists of four radical mastectomies performed under Pentothal Sodium alone. The second group consists of six radical mastectomies performed under Pentothal Sodium and supplemental intercostal novocain block. An interesting result of the combined method is that the surgeon becomes an active participant in the production of the anesthesia, since all novocain blocking is carried out by the surgeon via a transincisional approach after the incision has been made. By this method the surgeon may

†Surgeon, St. Vincent Hospital, Worcester.

matter of resourcefulness and ingenuity in locating difficult cases. Success in follow-up studies can be facilitated by preparing for them well in advance. It helps, for example, if the patient knows that such studies are contemplated or being made and that an effort will be made to check his progress periodically. It helps if, at the original visit or hospital stay, sufficient information is obtained—such details as the patient's business address in the case of employed persons, the school attended in the case of children and the given names of married women, together with the full name, age or date of birth and business and business address of the husband. In the case of patients who are referred by other physicians or who are seen in consultation, a cordial relation with these other physicians is invaluable, particularly if these men also know of one's interest in long-range studies of cases. Periodic communications with the patients or referring physicians are helpful. Finally, use may be made of outside agencies.

The importance of a high degree of completeness in follow-up studies cannot be overstressed. Failure to achieve this is a legitimate cause for questioning the validity of the results, because it is not safe to assume that untraced cases show the same general characteristics as do those that are traced, more particularly, if the number of untraced cases is disproportionate to the number of known deaths, the mortality figures are open to doubt.

Some groups are too large to make it practicable to follow up the entire number. In these circumstances, suitable sampling procedures are permissible. As an example, the last mortality tables computed for patients of the George F. Baker Clinic were based on a 25 per cent sample. Furthermore, the results of a systematically selected sample may differ widely from those based on an aggregate of unsystematic observations. An example of this is furnished by figures covering the average duration of disease and average age at death, as given in Tables 42 (page 275) and 44 (page 277) by Joslin et al.¹¹

Certain necessary precautions must be given concerning the analysis of clinical statistics on diabetes. Characteristics and results may be expected to differ among diabetic patients according to age, sex, incidence of complications and environmental factors, such as education and social status. Allowance should be made for these various factors, if possible. In any case, the general nature of the group should be described. One must also be careful to define fundamental terms or the nature of specific classes studied in order to assess results with sufficient accuracy and fairness. The definition of diabetes is not fixed. Frank cases cause little difficulty, but borderline cases, if they form a significant proportion of the series, may be the cause of otherwise unexplained differences. Similar considerations apply with regard to the definition of diabetic coma and gangrene.

In long-range clinical studies of diabetes, profitable use can be made of the life-table method of

analysis of mortality. The average duration of life from onset of diabetes to death is not an entirely satisfactory measure of the longevity of diabetic patients. This is seen most clearly with respect to diabetic children. Fatal cases among them are not typical of the group. Most diabetic children may be expected to outlive their physicians. It is therefore necessary in mortality studies of diabetic patients to consider the total population of such patients and the deaths that occur within it. From such data are computed death rates on an annual basis, in suitable categories by age and other characteristics. This method of analysis is described in a number of excellent texts and articles. Those deserving special mention are a book by Hill¹⁴ and a paper by Frost.¹⁵

* * *

It is too much to expect the physician to be a statistician with up-to-date knowledge of technical developments in this field. It is to the doctor's advantage, however, to have a knowledge of the fundamentals of statistics and statistical reasoning, and without too much trouble he can make himself familiar with a few basic statistical procedures. There are some textbooks on statistics that are especially designed for the physician, notably the volume by Hill already referred to. Those who are connected with or live near a large university would be well advised to make use of such professional statistical assistance as can be obtained there. In this way one is less likely to commit errors through faulty classification of data and to make unwarranted conclusions based on sparse data. The war has greatly stimulated work in practical and theoretical statistics. Consequently, statistical talent is now more abundant than ever before.

ANESTHESIA FOR RADICAL MASTECTOMY WITH INTRAVENOUS PENTOTHAL SODIUM AND INTERCOSTAL NERVE BLOCK*

JAMES C McCANN, M D †

WORCESTER, MASSACHUSETTS

THE increasing use of Pentothal Sodium as an important anesthetic agent during major surgical procedures is well attested in the current literature on methods of anesthesia. That its optimal usefulness with the greatest measure of safety is achieved when it is employed in conjunction with supplemental anesthetic agents is borne out by reports relating to such conjoint use or by those that discuss in passing the supplemental use of other agents. My¹ previous report discussed the combined use of intravenous Pentothal Sodium and local nerve block (splanchnic) in upper abdominal surgery. In this earlier study, in which a new splanchnic needle guide was described, the two major purposes sought by the novocain nerve block were, first, to provide flaccid paralysis of the rectus abdominis muscle and second, to obliterate the visceral sensory impulses by splanchnic nerve block. By this rational supplementation of Pentothal Sodium with novocain block, a sharp reduction in the quantity of the former required for anesthesia was accomplished.

As surgical experience under Pentothal Sodium is extended, it becomes more and more apparent that one is dealing with an unusual opportunity to study accurately the precise physiologic background of surgical anesthesia in human beings. This premise turns on the evident dominance of the neurogenic reflexes initiated by surgical trauma during Pentothal Sodium anesthesia in reflexly activating the respiratory center, on the specificity of the respiratory response to the surgical reflexes arising from the segmental subdivisions of the terminal cerebrospinal nerves—cervical, thoracic, lumbar and sacral, and finally on the repressive action of Pentothal Sodium on the reflexly activated center.

The first site of pharmacologic action by Pentothal Sodium is the cerebral cortex, whereby unconsciousness supervenes, the second site appears to be the thalamus, whereby all reflex motor response to surgical trauma is controlled as a result of suppression in this relay center of all sensory impulses directed toward the cortex, the third site of action is the respiratory center, whereby, in the absence of reflex stimulation from surgical trauma, there is a completely smooth graded depression of respiratory activity. Under the conditions of a surgical operation, however, painful (noxious) stimuli of constantly varying intensity are conducted from the

field of operation over the afferent limb of intact reflex arcs to the respiratory center. Depending on whether the inspiratory or expiratory neurons are specifically activated, the afferent limbs of the arcs carry back impulses that alter the character of respiration in a specific manner. Thus, the effective administration of Pentothal Sodium as an anesthetic agent resolves itself into an effort to achieve an optimal yet safe balance between the depressing action of this drug on the reflexly activated respiratory center and the stimulating action of neurogenic stimuli impinging on it that have been initiated by trauma in the field of operation. The goal sought in effectuating this balance is that of respiratory quietude without undue depression of respiration.

The introduction of novocain nerve block in anesthesia under Pentothal Sodium is directed at strategically placing the solution so as to interrupt transfer of noxious afferent stimuli centrally, thus minimizing the reflex stimulation of the respiratory center. By such a physiologic maneuver the intermittent demands for increased administration of Pentothal Sodium are eliminated and the total overall demand for the drug is sharply reduced. My experience during the last two years with the systematic combined use of these two methods of anesthesia has sustained experimentally in human beings the following generalization made in 1945 by Gordh:² "The more the physiology of anesthesia is studied, the more strikingly becomes the predominance of the part played by respiration. Indeed the physiology of respiration may be said to dominate the physiology of anesthesia."

The present study continues the report of my experiences with the combined use of Pentothal Sodium and local nerve block as a method of anesthesia in major surgical procedures. The present report specifically discusses the use of intravenous Pentothal Sodium combined with intercostal nerve block in the performance of radical mastectomy for carcinoma of the breast. It is based on a comparative study of two groups of cases. The first group consists of four radical mastectomies performed under Pentothal Sodium alone. The second group consists of six radical mastectomies performed under Pentothal Sodium and supplemental intercostal novocain block. An interesting result of the combined method is that the surgeon becomes an active participant in the production of the anesthesia, since all novocain blocking is carried out by the surgeon via a transincisional approach after the incision has been made. By this method the surgeon may

*Read by title at the postponed annual meeting of the New England Surgical Society, Boston, February 6, 1946.

†Surgeon, St. Vincent Hospital, Worcester.

place the novocain solution strategically, precisely and visually. Many surgeons, having been trained in the technic of novocain field block, have discarded it as a time-consuming, delaying method under conditions in which the surgeon must administer it himself in the course of a heavy surgical schedule. The use of this technic by the transincisional approach and in conjunction with Pentothal Sodium, however, restores novocain field block to the status of a precise, quickly executed technic, which proves of great value in the restricted physiologic roles herein demanded of it.

The method of combined intravenous Pentothal Sodium and intercostal nerve block in radical mastectomy is essentially simple. The patient is carried into a light third stage of surgical anesthesia with Pentothal Sodium, which permits a skin incision to be made. In this study the drug was administered in a 1 per cent solution according to the fractional drip method previously discussed. Using the Greenough modification of the Rodman incision, the posterior axillary incision is made and carried down to the ribs and intercostal muscles for the entire length of the operative field. The skin and subcutaneous tissues are dissected posteriorly beyond the point of emergence of the lateral cutaneous branches of the intercostal nerves. With the fingers of the left hand identifying each rib successively from the eighth or ninth upward to the fourth, a needle is advanced under the lower border of each rib until it penetrates the compartment between the external and internal intercostal muscles in which each intercostal nerve runs, and here 2 or 3 cc of a 1 per cent solution of novocain is deposited. The axilla is then dissected sufficiently to expose the upper four ribs and to identify and protect the axillary vessels and nerves, following which the four upper intercostal nerves are similarly novocainized. The deposition of novocain should be made posteriorly to the midaxillary line, which is the point of emergence of the lateral cutaneous branches of the intercostal nerves. By this transincisional method, a quick, accurate blocking of the intercostal nerves under vision may be easily accomplished in two or three minutes. The mastectomy may then be completed with need of but little more Pentothal Sodium.

In the first group of 4 patients, to whom Pentothal Sodium alone was administered without the use of nerve block, the drug had to be administered at the average over-all rate of 23 mg a minute for the duration of the entire procedure (induction, operation and closure). In the second group of 6 cases, in which Pentothal Sodium was supplemented by transincisional intercostal nerve block performed by me, the administration of the drug was sharply reduced to an average over-all rate of only 13 mg a minute, a reduction of nearly 50 per cent. In 1 case following establishment of the intercostal block, no further administration of Pentothal Sodium was required. In all cases in which intercostal nerve

block was established, minimal additional amounts of the drug were needed following the initial induction dose. As an example, a patient required 1 gm. (100 cc of 1 per cent solution) of Pentothal Sodium for induction, whereas after establishment of the intercostal block only 200 mg (20 cc) was needed over a period of one hour for the entire mastectomy. Although the number of cases in each group is small, nevertheless the dramatic reduction in this rate of utilization of Pentothal Sodium validates the conclusions drawn as to the importance of the supplemental use of local nerve block in the operative field. The significance of the intercostal block from the viewpoint of the physiology of surgical anesthesia is that the noxious impulses from the operative field were blocked, they were not conducted centrally and neither impinged on nor stimulated the respiratory center. As a consequence, patients were carried in a light plane of anesthesia with quiet, unstimulated respiration during the entire procedure.

DISCUSSION

The conclusion derived from these successive studies is that the fundamental base from which a consideration of the physiology of surgical anesthesia may properly proceed is the dominance of specific surgical reflexes in so far as they stimulate the respiratory center and activate the respiratory mechanism. This concept accurately integrates with the increasing recognition in recent years of the importance of neurogenic stimulation of the respiratory center, as contrasted with its chemical stimulation. The painful (noxious) stimuli of surgical trauma, whether from the somatic or visceral zones, are conducted centrally and impinge on the respiratory center, stimulating it to activity, preponderantly on the inspiratory or on the expiratory side. The type of response depends on the peripheral segmental representation of the cerebrospinal nerves in the field of trauma — whether cervical, thoracic, lumbar or sacral. The anatomic specificity of reflexes from the different segmental areas of operation has been recorded and demonstrated by me with pneumographic recordings.

The segmental character of the respiratory response to neurogenic stimuli initiated by surgical trauma may be briefly outlined as follows:

Cervical segment Little stimulation of the respiratory center is evident from surgical trauma in this area, as evidenced by observations made during thyroidectomies. Few opportunities were available for studying respiratory response during operations on the upper extremities. In 1 case, traction on an exposed median nerve sharply stimulated the center.

Thoracic segment The wide area of the body supplied segmentally by the intercostal nerves extends from the neck to the symphysis pubis. In all operative procedures in this segmental zone, in the somatic plane, the same characteris-

tic respiratory response is elicited and may be strikingly recorded by a pneumograph. There is a transient stimulation of the inspiratory phase of respiration. There is a sharp and prolonged stimulation of the expiratory phase, characterized by a succession of respiratory cycles in which the phase is intensified and prolonged for four to twelve seconds. In a few cases traction on the upper abdominal viscera has produced a nearly complete expiratory arrest. This prolongation of expiration is due to the fact that the expiratory phase has been converted from a passive to an active phenomenon. The accessory muscles of respiration, particularly the rectus abdominis, internal and external oblique and transversalis muscles, are reflexly and fully activated during expiration, so that they retract the lower ribs downward and inward during the expiratory phase for varying periods of time. In light planes of anesthesia this effort may be accompanied by an expiratory grunt. Increased quantities of Pentothal Sodium depress the more sensitive and reflexly stimulated expiratory neurons, doing so far in excess of the drug's depressing action on the inspiratory neurons. By this action the distorted inspiratory-expiratory ratio, which may be 1.5 or 1.6, is normalized and restored to the usual 1:1 ratio. At this point the accessory muscles are no longer activated, the expiratory phase returns to a passive state, and respiratory quietude again prevails. The reflexes from the thoracic segment when initiated in the skin and subcutaneous tissues may be blocked by novocain infiltration or by inhalation of nitrous oxide and oxygen. In the field of radical mastectomy they may be interrupted by an intercostal nerve block, when arising from the subdiaphragmatic visceral zone they may be interrupted by splanchnic block, and when arising from manipulation of the bowel they may be interrupted by mesenteric block. The peritoneal traction reflex, initiated during closure of the incision and transmitted centrally by the somatic intercostal nerves, may be easily suppressed by small quantities of cyclopropane or of nitrous oxide and ether. The more profound visceral and peritoneal traction reflexes are not controlled by inhalation of nitrous oxide and oxygen alone with Pentothal Sodium.

Lumbar segment The reflex stimulation of respiration from the zone of lumbar-nerve distribution is mild as compared with that from the thoracic zone. There is a mild increase in the rate and amplitude of both inspiration and expiration, the normal ratio of the two phases is preserved, expiration does not become an active phase, so that the accessory abdominal muscles of respiration are not activated, and abdominal quietude is consequently not disturbed. The lumbar reflex may be demonstrated by traction on the superior hypogastric plexus during a pre-

sacral neurectomy. This reflex may be obliterated by novocain block above the level of traction. In clinical surgery this reflex is not often encountered. It is generally seen in the presence of extensive pelvic inflammatory disease or endometriosis, when the adnexa have to be forcibly separated from the pelvic parietal peritoneum. In the somatic area the reflex may be noted during operations on the lower extremities in the zones of lumbar-nerve distribution. This reflex is quite easily controlled by small additional quantities of Pentothal Sodium.

Sacral segment The sacral reflex is strikingly characteristic and different from the reflexes elicited in the other segmental zones. It arises only from the deep pelvic zones in cervicovaginal regions in the female and in the prostatic regions in the male. During pelvic surgery strong traction on the cervical region may evoke a single prolonged inspiratory effort, accompanied by a loud inspiratory moan due to reflex laryngospasm. No succession of repeated respiratory responses is established as is characteristic of the thoracic and lumbar reflexes. The sacral reflex may be blocked by novocain placed deeply in the curve of the sacrum or by infiltration of the uterosacral ligaments at their point of attachment to the cervix. These ligaments have in this manner been experimentally revealed as the pathway for transfer of the sensory nerves responsible for this distinctive sacral reflex. This reflex may also be elicited from trauma to the penis during a circumcision, by impulses transmitted over the dorsal nerve of the penis to the internal pudendal nerve and thence to the sacral plexus. In the somatic areas the reflex may be elicited over the saddle area of distribution of the sacral nerves in the region of the anus, inner thigh, vulva and scrotum. The sacral reflex has no significance in so far as quietude of the operative field is concerned. Its constant repetition may, by virtue of its noisy laryngospasm, be a source of annoyance to the surgeon and the anesthetist.

SUMMARY

Further experiences with the use of combined intravenous Pentothal Sodium and local nerve block anesthesia are presented. A previous report described the sharp reduction in the rate of utilization of Pentothal Sodium for upper abdominal surgery following the supplemental use of splanchnic nerve block. In the present study a comparable sharp reduction in the rate of utilization of the drug during radical mastectomy for cancer of the breast following the supplemental use of intercostal nerve block is reported. This observation is related to the physiology of surgical anesthesia in so far as the quantity of Pentothal Sodium required for a satisfactory anesthesia is directly proportionate to the amount needed to repress the activated respiratory

center, which has been reflexly stimulated to over-activity by noxious stimuli arising from the operative field. By the strategic use of novocain block by a simplified transincisional approach, these stimulating impulses are prevented from reaching and activating the respiratory center. Thus, the excessive demand for Pentothal Sodium to control the reflexly stimulated center sufficiently to restore respiratory quietude is circumvented.

A brief résumé of the specific segmental character of the surgical reflexes and respiratory response evoked from the different body areas has been given, in so far as they evoke a characteristic response from the respiratory center. These have been recorded by pneumographic tracings.

A general statement with reference to the combined use of the two methods of anesthesia may be made. On the basis of a physiologic integration of methods, the Pentothal Sodium induces quiet sleep that is free from any excitement, it provides a quiet respiration, by repressing the stimulation of the respiratory center from the less intense surgical reflexes, it provides a comfortable recovery period singularly free from nausea and vomiting and from

pulmonary complications. Strategic transincisional novocain block provides relaxation of muscles, it may be used to block massive reflex impulses from stimulating the respiratory center, — intercostal, splanchnic, mesenteric or pelvic block, — thus reducing the demands for large quantities of Pentothal Sodium. The terminal use of small quantities of cyclopropane or of nitrous oxide and ether to control the peritoneal traction reflex at the time of closure of the incision eliminates the final large peak demand for Pentothal Sodium, thus contributing to the early awakening of the patient.

This rational integration of methods in terms of the basic physiology of surgical reflexes and respiration during anesthesia and surgery has provided an eminently safe and satisfactory method of anesthesia for over 70 per cent of general surgical operations.

MEDICAL PROGRESS

ACTIVE IMMUNIZATION (Continued)

GEOFFREY EDSALL, M.D.*

BOSTON

PERTUSSIS

Despite the fact that infant deaths from pertussis have decreased 70 per cent in the last forty years, it remains the most frequent cause of death among the acute contagious diseases of early childhood. "The concentration of deaths in the first two years of life, especially under six months, is constant for all parts of the United States."¹⁹³ A recent editorial¹⁹⁴ points out that in Massachusetts from 1924 to 1943, 58 per cent of all deaths from this disease occurred in the first year of life, and 84 per cent in the first two years. Furthermore, the disease in older children, although rarely fatal, is frequently prolonged and debilitating, and involves much time lost in isolation and away from school. Hence there is ample justification for the numerous attempts that have been made to control the disease by means of immunization.

During the last fifteen years, beginning with the work of Leslie and Gardner¹⁹⁵ on the antigenic phases of *Haemophilus pertussis*, the principles underlying artificial immunization against whooping

cough have been sufficiently elucidated to make possible the production and use of vaccines that, in most of the studies reported, protected a large majority of the persons immunized. The development of pertussis vaccination up through 1942 has been reviewed by both Lapin¹⁹⁶ and Felton and Willard.¹⁹⁷ With few exceptions, the studies reviewed have demonstrated in large groups of children that the communicability rate of pertussis in persons vaccinated with 70 to 120 billion killed, whole, virulent pertussis bacilli is much less than the expected rate as determined by experience in unvaccinated children. Similar results are found in the more recent reports of Bustamante,¹⁹⁸ Galvin and Wampler¹⁹⁹ and Garvin.²⁰⁰ Moreover, attempts to evaluate the severity of the pertussis occurring in both groups, generally revealed that fewer severe cases occurred in the vaccinated than in the control groups. These findings have in general indicated that vaccination resulted in from 75 to 90 per cent protection. Such field studies have been criticized, on the basis that the unvaccinated groups used for comparison were not valid controls.²⁰¹ This criticism has in some cases been justified, and it is fair

*Director, Division of Biologic Laboratories, Massachusetts Department of Public Health, instructor in bacteriology and immunology, Harvard Medical School.

to demand that the study and control groups be submitted to an independent test of random selection, such as a comparison of the incidence of other communicable diseases in both groups.^{202, 203} An interesting method of analysis is that of Sargent and Merrell, which has been applied to pertussis immunization by Weiss and Kendrick.²⁰⁴ They compared the incidence of pertussis among immunized and nonimmunized children under ten years of age reported during a given period as having contracted scarlet fever, measles, chicken pox or pertussis. From these data and from the pertussis immunization files, it was possible to compare the expected incidence of pertussis, if the immunization had been of no value, with the actual incidence. Only 15.8 per cent of the expected cases occurred in the immunized group. In passing it should be noted that the 34.8 per cent attack rate, sometimes cited²⁰⁵ from Kendrick and Eldering's major study²⁰³ as being in essence a failure, occurred among children experiencing intimate exposure to the disease — the control group showing a communicability rate of 89.4 per cent. To be fairly evaluated, such figures should be compared with similar studies of the effectiveness of a generally accepted bacterial vaccine in the presence of an equally high attack rate among the controls. Such a comparison would be difficult, for few bacterial infections occur under conditions leading to a 90 per cent attack rate.

Except for the widely discussed study of Doull et al.²⁰⁶ in Cleveland ten years ago and the subsequent unfavorable one of Siegel and Goldberger,²⁰⁷ most reports indicate that a significant degree of protection is obtained with pertussis vaccine. The failure of the Cleveland immunization program has been generally attributed to the fact that the vaccine was washed in distilled water, a procedure since suspected of being injurious to the antigen and not employed in any other major study until the recent British trial of pertussis vaccine reported by McFarlan et al.²⁰⁸ who apparently used an ample vaccine dosage as judged by bacterial counts and whose study was well controlled. Among 350 vaccines the incidence of pertussis scarcely differed from that in the control group. On the basis of these findings and those of Doull et al. and Siegel and Goldberger, a concurrent editorial²⁰¹ concluded that the favorable reports of the last ten years are open to question. The editorial ignored or minimized the facts that the British vaccine was grown on horse-blood medium, which has been shown to favor rapid loss of antigenicity in *H. pertussis*,²⁰⁹ that the studies of McFarlan and Doull and their associates — the only two in which the vaccine was washed in distilled water — represent two of the three important failures of pertussis vaccination in the last decade, and that the British vaccine was held in phenolized distilled water at icebox temperature for a week, which would presumably have accentuated whatever injury may be done by distilled water. The bur-

den of proof appears to lie with those who do not consider washing in distilled water to be harmful, in any event, a comparable study is now being carried out in England, using a generally accepted vaccine of American make.

Undoubtedly there is considerable room for improvement in pertussis vaccines and vaccination. The protection rate, although it may be highly satisfactory from an epidemiologic point of view, is not entirely so to the practicing pediatrician. The chances of protection cannot well be enhanced by an increase in the dosage of the standard vaccine, which is already high in volume (up to 7 cc in some schedules), in numbers of bacteria (70 to 120 billion) and in numbers of doses (three to five), also, the procedure is followed by a relatively high incidence of local and general reactions. On the other hand, the dosage cannot wisely be reduced. There are, however, various ways of increasing the effectiveness per unit dose of the vaccine. Lapin et al.,²¹⁰ Miller and Saito,^{211, 212} Coppolino²¹³ and Mishulow et al.²¹⁴ favor intervals of two to four weeks between doses. Although no comparative clinical studies have proved that a longer interval yields superior protection, such a supposition is reasonable in the light of numerous studies on other immunizing procedures cited elsewhere in this review.

Alum-precipitated pertussis vaccine was introduced several years ago by Harrison, Franklin and Bell,²¹⁵ who found a single dose of 10 billion organisms prepared in this fashion to be insufficient, Bell²⁰² subsequently showed, however, that two such doses at an interval of four weeks gave a high level of protection, and similar results were obtained by Kendrick.²¹⁶ The use of aluminum hydroxide absorption has recently been reported,²¹⁷ and may represent a possible improvement over alum precipitation, since the reactions appear to be somewhat milder.

Until recently, all successful pertussis vaccines were prepared on some modification of the classic Bordet-Gengou type of blood-starch-agar medium, either human (Sauer) or sheep (Kendrick) blood being used. Hornibrook²¹⁸ had shown that *H. pertussis* could be sustained in Phase I for several generations in a liquid medium of relatively simple composition. Wilson,²¹⁹ Taylor and Farrell²²⁰ and Cohen and Wheeler²²¹ introduced successive improvements, so that rapid adequate growth of a virulent, antigenic form of the organism can be obtained in this type of medium without the necessity of introducing red blood cells or foreign protein in any other form. Such a medium approaches the ideal for its purpose, since it minimizes the chances of inducing untoward reactions to substances of high molecular weight while retaining a maximum of the antigenic material present in the original growth.

The numerous attempts to evaluate the significance of the toxins of *H. pertussis* have been well reviewed by Lapin.¹⁹⁶ Several recent studies lend sup-

port to the long established belief that a toxic factor contributes to the pathogenesis of pertussis Sprunt and Martin²² showed that the edema, necrosis and mononuclear reaction that can be induced in rabbit lungs by pertussis toxin could be prevented by an antitoxin produced in rabbits Ospeck and Roberts²³ found that the same antitoxin furnished more effective protection against live *H. pertussis* cultures than an antibacterial serum Evans,²⁴ in a carefully controlled study, presented evidence that parenterally administered pertussis antitoxin offered little protection against pertussis bacilli introduced intranasally, whereas intranasally applied antitoxin exerted a more marked protective action than an antibacterial serum Such findings suggest that antitoxic titers in human beings should bear some relation to resistance to pertussis, but a study in patients convalescing from pertussis showed that detectable titers were rarely found²⁵ Moreover, an intradermal susceptibility test based on Streaus's²⁶ endotoxin failed to reveal a definite correlation either with a history of pertussis or with previous vaccination²⁷ Finally, the detoxified pertussis antigen developed by Roberts and his associates, when submitted to a recently reported field trial, did not appear to afford significant protection²⁸ One must conclude, therefore, that the role of the toxic factor in susceptibility or resistance to pertussis infection has yet to be elucidated

The combination of pertussis vaccine with other antigens was first suggested ten years ago by Bordet²⁹ It has been shown in animals³⁰ and in man³¹ that the two antigens exert no mutual interference as judged by laboratory measurements of antibody response Kendrick³² and Sauer³³ and their associates carried out field studies in which alum-precipitated combined pertussis vaccine and diphtheria toxoid was used Both groups found that the mixture gave protection against pertussis and yielded a high proportion of Schick-negative subjects Lapin³⁵ and Miller and Saito³² suggested the addition of tetanus toxoid to the immunization against diphtheria and pertussis, considering various combinations and schedules that could be used with this in view³² Lapin concluded that the best results, as judged by laboratory tests, and the fewest reactions were obtained by the administration of the pertussis vaccine alone and the combined toxoids as separate injections either concurrently or later, he³⁶ noted elsewhere that the triple combination induced a large percentage of severe reactions and alum abscesses Many physicians have confirmed his observation that the combined irritating effects of pertussis vaccine and alum — perhaps potentiated by the presence of toxoid — tend to produce an undesirably high incidence of local inflammatory reactions and not a few abscesses Hamilton and Knouf³⁷ recently reported the use of a fluid triple preparation, with apparently excellent results and few reactions Such a prepara-

tion may offer a satisfactory means of inducing simultaneous immunity to diphtheria, pertussis and tetanus, with a minimum of injections and reactions Some clinicians, however, preferring to follow Lapin's findings, administer the pertussis vaccine first and the combined toxoids subsequently This schedule has the advantage of placing the pertussis immunization at the earliest possible date, when it is most needed Use of triple vaccine-toxoid at this early date has the disadvantage that the infant's response to diphtheria toxoid is likely to be less satisfactory than it is a few months later³⁸

The use of a booster dose to maintain or restore immunity to pertussis in a previously vaccinated subject has an excellent theoretical basis but has not yet been submitted to any adequate clinical trials Nevertheless, the antibody responses following booster injections are so striking and so well sustained³⁸ ³⁹ that there is every reason to believe that the procedure is a valuable one The analogy with other immunization procedures that have been more thoroughly studied suggests that the response to a booster dose of pertussis vaccine most frequently reaches its peak in ten to fourteen days and is therefore effective in protection just before or perhaps even after actual exposure On the other hand, primary vaccination against pertussis is of doubtful value during an epidemic or after exposure Several studies suggest that some degree of protection is obtained even under these circumstances,¹⁹ ⁴⁰ ⁴¹ but such findings are by no means unanimous⁴²

The protection of young infants against pertussis has presented a particular problem, ever since it was shown that the response to vaccination — as with most other immunizations — was less satisfactory in the first than in the second half of the first year of life Sauer's⁴³ experience supported this finding and led him to recommend against immunization in the first six months of life Sako et al,⁴⁴ however, reporting on the immunization of almost 4000 infants less than three months old, observed a communicability rate, in family exposures, of only 19 per cent, in contrast with one of 92 per cent in the control group Sako's exceptionally good results, which may not be reproducible in a more inclement climate, appear to justify immunization against pertussis at an earlier age than has been customary

Another attack on this problem is the immunization of pregnant mothers, recommended by Cohen and Scadron,⁴⁵ Mishulow et al⁴⁶ and Kendrick and her co-workers⁴⁶ The antibody titers obtained in mothers and transmitted to their infants suggest that some protection is induced by this method

TYPHOID FEVER

Evidence of the efficacy of typhoid vaccination is found in several recent reports Martel⁴⁷ describes a localized typhoid epidemic in an outlying district of the Province of Quebec, where the number of

ases fell from 35 in the year before vaccination was begun to 17, 5 and 1 respectively in the succeeding three years. Callender and Luippold,²⁴⁸ Murphy et al.²⁴⁹ and Duncan and his associates²⁵⁰ report outbreaks of typhoid fever among significantly large vaccinated and unvaccinated groups, subject to identical and simultaneous risks of infection, so that the efficiency of the vaccine could be determined. The respective incidence of the disease in each outbreak was as follows: 55 cases among 4000 vaccinated soldiers as against 56 cases among 800 unvaccinated civilians (14 vs 7.0 per cent), 8 cases among 170 vaccinated civilians as against 61 cases among 531 unvaccinated civilians (4.7 vs 11.5 per cent), and 1 case among 180 vaccinated SPARS as against 17 cases among 194 unvaccinated civilians (0.5 vs 8.7 per cent).

It is apparent that immunization against typhoid fever — like virtually all other immunizations — affords a marked but not absolute degree of protection. As one would anticipate, numerous reports of typhoid fever in immunized persons have appeared during recent years.²⁵¹⁻²⁵⁴ All reports stress the atypical nature of the disease in immunized persons, and two observers report a relatively high incidence of complications in such cases.^{252, 254} — a finding that may well be related to the difficulty, and hence the delay, experienced in making the diagnosis. Gav,²⁵⁵ almost thirty years ago, wrote

It may well be questioned why further modification of typhoid vaccine should seem necessary in view of the extremely good protective results that have already been obtained in certain large groups of individuals. The only answer to such questions is and must ever remain that the theoretical considerations based on the understanding of underlying principles will ever precede all practical advances.

Although Smith and Reagh²⁵⁶ had called attention to the dual nature of certain bacterial agglutinins as long ago as 1903, little attention was paid to this phenomenon until the demonstration of the separate identity of O and H agglutinins by Weil and Felix.²⁵⁷ Arkwright²⁵⁸ later demonstrated the close relation between smoothness and virulence of cultures of *Eberthella typhosa*, and their ability to produce O agglutinins and confer protection on guinea pigs through vaccination. Grinnell showed that vaccines prepared from smooth virulent cultures induced bactericidal antibodies²⁵⁹ and protected mice against lethal quantities of live bacilli²⁶⁰ to a degree far beyond what could be achieved by vaccination with rough, avirulent cultures. These findings were followed by the studies of Perry and his associates²⁶¹ of the Royal Army Medical Corps, and Siler and his co-workers,²⁶² of the United States Army Medical Corps, as a result of which virulent strains were substituted for the classic Rawlings strain used in vaccine production. The United States Army group²⁶² subsequently carried out numerous and fundamental studies on methods of evaluating typhoid vaccine.

It is of practical consequence to the physician that these studies and similar investigations elsewhere have provided the basis on which the National Institute of Health four years ago set up minimum requirements for typhoid vaccine entering interstate commerce in the United States.²⁶³ These provide that such vaccines shall be prepared from cultures derived from or antigenically equivalent to the Panama 58 strain of *E. typhosa*, which was selected from among many strains for its high degree of virulence, antigenic composition and immunizing power and which immunizes successfully against strains of *E. typhosa* collected from widely separated parts of the world.²⁴⁸ The other principal feature of the minimum requirements is a mouse-vaccination test that, although simple to perform, is sufficiently rigid to exclude the poorer grades of vaccine. Griffiths,²⁶⁴ Luippold²⁶⁵ Shaffer et al.²⁶⁶ and others have refined the protection test so that it can be used to distinguish relatively small differences in potency, such as those resulting from minor variations in methods of preparing vaccines. It should be noted that the satisfactory performance of a mouse-protection test for typhoid vaccine depends on the use of the mucin suspension technic^{267, 268} and that tests performed without the use of mucin, although of some value, are less easy to interpret, thus the low value that Felix²⁶⁹ placed on the protection test might have been modified had he employed the mucin technic.

There is no unanimity regarding the best procedure to be employed in the preparation of typhoid vaccine. The classic method is to heat the vaccine at 53 to 56°C for about sixty minutes and then to add 0.25 per cent Trikresol or an equivalent phenolic preservative. Both heat and phenol are known to be deleterious to many antigens, and a controversy has long existed concerning their effect on typhoid vaccine. Rainsford^{270, 271} Siler and his co-workers,²⁶² Felix,²⁶⁹ Ungar et al.,²⁷² Shaffer et al.,²⁶⁶ Levinson²⁷³ and others employed silver ion, formalin, acetone, chloroform, alcohol, Merthiolate and ultraviolet irradiation for inactivation of the vaccine, the product obtained being in most cases superior in immunizing potency to the classic preparation. Meanwhile, scattered attempts have been made to prepare and evaluate typhoid vaccines modified by the addition of alum²⁷⁴ or the inclusion of an endotoxoid factor^{275, 276}, sufficient data to judge the merits of these modifications are not yet at hand.

The preparation of purified typhoid antigens, free from the extraneous substances present in the whole bacillus, has been the object of numerous investigations and, if accomplished, might aid in the elimination of the untoward side reactions that are the bane of typhoid vaccination. Such an approach must be preceded by a precise definition of the various antigens required for effective immunization and of the role played by each. It was shown some years ago²⁵⁸ that, of the two classically described O and H antigens, only the former was definitely con-

cerned in protection against typhoid infection Felix and Pitt²⁷⁷ described a third antigen, closely associated with virulence and designated by them as the V₁ antigen, whose role in protection against infection has not been clearly defined, although it has been shown to possess high immunizing potency in mice.^{278, 279} Felix proposed the concept that it stimulated resistance to bacterial invasion, whereas antibodies to the O antigen protected the host against the toxic effect of large quantities of typhoid bacterial substance. This concept has been supported by quantitative studies.²⁷⁹ Nevertheless, the high efficiency of typhoid vaccines, most of which are prepared in a manner supposed to destroy the delicate V₁ antigen, remains to be explained.

Various investigators have prepared relatively pure concentrates of the immunizing antigenic substance of typhoid bacilli.²⁸⁰⁻²⁸⁶ Such preparations consist primarily of a complex polysaccharide, with an immunizing potency several thousand times that of the original vaccine, weight for weight. This active substance, which is stable and filterable, appears to be somewhat less toxic, per unit of immunizing potency, than the original vaccine. Treffers²⁸⁷ recently showed that the toxicity of this substance can be greatly reduced by acetylation with acetic anhydride. Such preparations, because of their inherent advantages, would rapidly become generally used except that, as with chick-embryo smallpox vaccine, they must compete against a product that has been amply proved to be effective against actual clinical infection. It will therefore take a bold spirit to induce the medical or public-health professions to try purified typhoid antigens on a significantly large scale.

The standard dosage of typhoid vaccine — 0.5, 1.0 and 1.0 cc subcutaneously, usually at intervals of seven to ten days — has scarcely been questioned since its establishment. Bensted²⁸⁸ advocated diminishing the dosage for civilian immunization, simply to reduce the incidence of side reactions. The ritualistic observance of the usual interval is no longer adhered to, and the United States Army regulations now permit the resumption of an interrupted course of immunization instead of repeating it in its entirety, as was formerly required. Although evidence is lacking, extensive experience with other types of immunization indicates that longer intervals between doses of typhoid vaccine would doubtless give an immunity superior to that obtained with one-week intervals.

Intradermal immunization has had its advocates since it was first proposed by Tuft.²⁸⁹ Of the numerous subsequent studies of this method,²⁹⁰⁻²⁹⁴ all but two^{291, 294} evaluated the results only by agglutinin titrations. All observers reported milder reactions following intradermal immunization, Van Gelder and Fisher,²⁹² who obtained poorer agglutinin titers following intradermal injection, nevertheless considered the reduced reactions sufficient to render the

intradermal method superior to the subcutaneous method for typhoid immunization. Tuft²⁹¹ and Luippold²⁹⁴ employed mouse-protection tests for evaluating the results. Their findings conflict, and further studies may be required to determine the usefulness of this method for primary immunization.

Largely because of the theoretical and experimental support that oral antityphoid immunization received from the work of Besredka,²⁹⁵ this method has been rather widely employed. Recent reports indicated that little, if any, agglutinin formation^{296, 297} and no detectable mouse-protective antibodies²⁹⁸ followed its use. General opinion among immunologists is that the procedure as at present employed is of little value. It is hardly surprising that a report of intranasal typhoid immunization²⁹⁹ yielded equally negative results.

Reimmunization against typhoid fever, as instituted in the United States Army a generation ago, consisted of a repetition of the initial immunizing course at three-year intervals. In the light of the knowledge of the time, this was a sound procedure. Subsequently, agglutinin studies showed that the antibody response to reimmunization was superior to that following the initial course of vaccine.²⁹⁹ This was confirmed later by mouse-protection studies,²⁹² which also demonstrated the correctness of Perry's observation²⁹⁰ that a single dose of vaccine, either 0.5 cc subcutaneously or 0.1 cc intradermally, was sufficient to reawaken a formerly established immunity. Furthermore, it appeared that such a single dose was effective even in persons who had not been revaccinated for a number of years.³⁰⁰ It is therefore generally recommended that persons who have had one course of primary antityphoid immunization no longer need to repeat a complete course periodically, but may maintain an adequate degree of protection by means of periodic single doses of vaccine, either 0.5 cc subcutaneously or 0.1 cc intradermally. The latter procedure apparently is the more effective of the two,^{292, 300} but for practical purposes the subcutaneous route is frequently adopted. To maintain a high level of immunity, such single booster doses should be administered annually,³⁰⁰ but as suggested above, almost all subjects who have had no typhoid immunization for many years show a vigorous antibody response following a single booster dose.

Combined immunization, several antigens being given in a single dose, may be said to have been established with the use of typhoid-paratyphoid A and B vaccine during World War I. Such mixtures were extended, particularly in the British armed forces, to include cholera vaccine, and favorable reports on such multiple combinations have appeared in Germany.³⁰¹ Quantitative studies on the comparative immunizing potency of such mixtures of enteric vaccines were made on typhoid-paratyphoid A and B vaccine by Longfellow and Luippold,³⁰² who observed that it appeared to produce a lower

level of antityphoid immunity than that noted in earlier studies using monovalent typhoid vaccine. Although the two studies are not strictly comparable, the findings suggest that the relative efficacy of the various combinations in current use should be re-investigated. Several years ago it was suggested, on the basis of United States Army statistics, that immunization with typhoid-paratyphoid A and B vaccine provided some protection not only against the designated infections but also against various milder forms of diarrheal disease.³⁰³ This seems to be a reasonable possibility, in the light of current knowledge of the antigenic structure of the various strains of the paratyphoid group. Longfellow and Luippold,^{304, 305} using mouse-protection tests, offered evidence that such protection is directly related to the antigens shared by the organisms. Thus it may be possible, by careful selection of organisms having an appropriate antigenic pattern and quality, to prepare a vaccine providing cross-immunity against a relatively large number of clinically infective strains. Clinical evidence of the efficacy of the paratyphoid components in preventing paratyphoid A or B fevers, however, has not been established on as sound a basis as has been done for typhoid vaccine, Syverton et al.³⁰⁶ in a recent report on an outbreak of paratyphoid A in military personnel, contributed pertinent observations on this question.

Typhoid or typhoid-paratyphoid vaccines have been combined with diphtheria or tetanus toxoids, or both,^{147, 307, 308} with no evidence of loss and some reports of definite increase in effectiveness. Such combinations have practical value for military purposes, and also, in a limited way, for certain civilian needs.

Reactions to typhoid vaccination have always represented a major obstacle to the use of this procedure, especially among civilians. As noted above, Bensted²⁸⁸ suggested that this difficulty be met by reduction in dosage, but there is no published evidence of the immunizing efficacy of less than the standard doses of the vaccine. Over twenty years ago, following the suggestion of Dr Béla Johan, of Hungary, the Massachusetts Antitoxin and Vaccine Laboratory effected a definite reduction in the incidence of reactions by centrifuging the crude vaccine, discarding the supernatant and resuspending the sediment in cresolized, buffered saline solution. Two decades later, however, the mouse-protection test showed that such a preparation possessed but a marginal immunizing potency. The method of inactivating the vaccine was revised, Merthiolate being substituted for heat and Trikresol, with a resultant marked increase in potency.²⁸⁶ No data are yet at hand to determine the comparative reactions produced by the current product. The studies of Morgan^{284, 286, 309} and others suggest that chemical separation of the toxic from the antigenic component of typhoid vaccine may be difficult if not

impossible, the final solution of the problem may therefore lie in detoxification.²⁸⁷ Some such change in the fundamental nature of the vaccine must be sought; if it is to receive the general acceptance that must at times be required.

An occasional local reaction is the appearance of a small granulomatous reaction at the site of an intradermal inoculation of the vaccine.³¹⁰ Such reactions may be of cosmetic importance in females, but are of little significance otherwise. Various other reactions are ascribed to the vaccine from time to time. The report of Toomey and Tischer,³¹¹ suggesting that typhoid vaccination may increase susceptibility to poliomyelitis, is too limited in scope to be regarded as significant without further study. The risk of inducing so-called "provocative typhoid" by vaccination in the presence of incipient infection was long maintained by some observers, being emphasized by no less an authority than Topley.³¹² Fitzgerald's³¹³ skepticism regarding this phenomenon, however, is shared by many of those experienced in the control of the disease.

(To be concluded)

BENJAMIN CASTLEMAN, M D, *Associate Editor*

EDITH E PARRIS, *Assistant Editor*

CASE 32351

PRESENTATION OF CASE

A forty-six-year-old housewife entered the hospital because of abdominal pain.

The patient had had three pregnancies, after each of which she noticed some weakness of the legs and a staggering gait. Seven years before entry, following the last pregnancy and a subsequent panhysterectomy for placenta accreta, these symptoms persisted and gradually progressed. Numbness and paresthesia in the legs, nocturnal back pain and poor sphincter control also developed. The patient was seen at this hospital three years before entry, when neurologic examination revealed slight spasticity of the arms and moderate spasticity of the legs, without paralysis or weakness. She also had a band of hyperesthesia to pinprick from the third to the sixth rib, as well as absent vibratory sense and poor position sense in the lower extremities. The Romberg test was positive. The heel-to-skin test was poorly performed. The deep tendon reflexes were all hyperactive. The plantar reflexes were extensor on both sides, and there was a Hoffmann sign on the left. Physical examination was otherwise negative, except for some resistance to deep palpation and slight tenderness in the right upper quadrant, with a questionable freely movable mass just to the right of and extending from the umbilicus upward to the right costal margin. A diagnosis of multiple sclerosis was made, and the

patient was followed in the Out Patient Department. The symptoms continued to increase gradually, and several weeks before entry she began to notice numbness in the hands. During the year before entry a gradual increase in the size of her abdomen, accompanied by occasional vague dragging sensations, had been noticed. Ten days before entry a tight feeling had developed in the abdomen, and the dragging sensations had become painful. Four days later the patient began to have sharp pains in the right lower quadrant every time she exerted herself or moved the abdomen. These pains gradually grew worse, and the entire right side of the abdomen became tender. She also lost her appetite and ate very little, but she did not vomit. During the four days before entry the abdomen had shown a sudden further increase in size until she was unable to button her coat. She had had normal bowel movements every day, including the day of admission.

Physical examination revealed a somewhat pale woman in moderate distress. The heart and lungs were normal. A large irregular, elongated tender mass filled the entire right side of the abdomen from the costal margin to the pelvic brim. It was not possible to feel between this mass and the liver at the right costal margin. The mass appeared to move with respiration. Peristalsis was present. Vaginal examination revealed a small freely movable, slightly tender cervical stump. The neurologic findings were essentially similar to those of the previous examination, with a slight progression.

The temperature was 101°F, the pulse 88, and the respirations 18. The blood pressure was 128 systolic, 78 diastolic.

Examination of the blood revealed a hemoglobin of 12 gm and a white-cell count of 10,600, with 84 per cent neutrophils. The urine was normal.

A plain film of the abdomen revealed a considerable amount of gas and fecal material in the large bowel, particularly in one isolated loop lying in the midabdomen (Fig 1). There was an ill-defined soft-tissue mass in the right lower abdomen. In the standing position no air was seen under the diaphragm, and no fluid levels were visible within the bowel loops.

An operation was performed on the second hospital day

DIFFERENTIAL DIAGNOSIS

DR FRANKLIN G BALCH, JR May we see the x-ray films?

DR JAMES R LINGLEY In all the films there is a great deal of gas in the colon and the dilated

mass I cannot in any way connect the mass in the right side with the diagnosis of multiple sclerosis, and the nature of the right-sided mass must therefore be explained Seven years before admission a panhysterectomy had been performed According to my ideas, a panhysterectomy is a total hysterectomy, including the uterus, both ovaries and tubes. Later in the physical examination, however,

FIGURE 1 Plain Film of Abdomen

loop mentioned in the record looks like an enormously distended, dilated and inverted cecum. The mass is questionable, although there is increased density in that region. One might explain the dilatation of the cecum by the mass obstructing the ascending colon.

DR BALCH This is essentially the problem of a forty-six-year-old woman with a definite diagnosis of multiple sclerosis and a right-sided abdominal

the cervix is mentioned, and I wonder whether the ovaries were removed.

DR W P GIDDINGS We were told that the ovaries had been removed.

DR BALCH Under those circumstances an ovarian cyst can be excluded. That is the likeliest diagnosis for a tumor in the right side, except that it extended up to the costal margin.

Localized ascites is unusual, and I do not entertain that diagnosis seriously

Diseases of the liver and gall bladder must be considered. It was stated in the record that the examiner could not palpate between the liver and the mass. That does not mean that the mass necessarily arose from the liver. Echinococcal cyst in the liver is a possibility, but no mention is made about where the patient had lived and no echinococcal complement-fixation test was done, so that the data are insufficient to warrant that diagnosis.

There is a possibility that hydrops of the gall bladder was present, but the history is too long and drawn out for such a diagnosis. If the statement is correct, and I assume that it is, the patient noticed a gradual increase in the size of the abdomen for a year. The same objection holds true for empyema of the gall bladder. Furthermore, she was not sick enough for an empyema and the pain was in the right lower quadrant and not the right upper quadrant, as one would expect with gall-bladder disease, which I believe can be ruled out.

What other form of cyst or tumor could this have been? A solitary cyst of the lower pole of the kidney is a possibility. The x-ray studies do not suggest it, although sufficient gas was present to obscure such a lesion. No investigation was made of this possibility, and I expect that such a lesion would have been felt on physical examination. Cyst of the pancreas occurs higher up and is closer to the midline. That diagnosis is therefore unlikely.

The history certainly does not suggest an intrinsic bowel lesion, such as intestinal obstruction. The bowel movements were normal up to the day of admission, and the pains were not typical of intestinal obstruction. The x-ray films are quite confusing, because I cannot figure out, if the cecum was dilated to that extent, why there were no symptoms of obstruction. There was probably subacute obstruction.

Cyst of the omentum, which is a rare lesion, is another possibility, but it would not account for the x-ray findings.

I am inclined to believe that a mesenteric cyst fits the picture better than any other single diagnosis. The symptoms persisted for a long time, and mesenteric cyst, of course, grows to large proportions. To be sure, such a lesion is usually not confined to the right side, but adhesions from the previous operation could have prevented the tumor mass from extending over to the left side and could also explain the enlargement. Bleeding into the cyst would account for the increase in the size of the cyst a few days before entry. I cannot make a positive diagnosis, but my guess is that this woman had a mesenteric cyst possibly causing partial obstruction.

DR. LINGLEY: Was the mass hard or soft?

DR. GIDDINGS: It was fairly firm, it appeared in part to be tympanitic.

DR. LINGLEY: I wonder if the mass felt three years previously could possibly have been the cecum—an anatomic variation of the cecum that had become twisted.

DR. BENJAMIN CASTLEMAN: Do you mean a volvulus of the cecum?

DR. LINGLEY: Yes.

DR. CASTLEMAN: Dr. Giddings, would you give us your impression of the case?

DR. GIDDINGS: We were as confused as Dr. Balch. We knew that the ovaries and the appendix had been removed. We entertained many of the diagnoses that Dr. Balch has mentioned, namely, mesenteric cyst, retroperitoneal cyst and tumor. On the basis of the x-ray evidence we were led to favor a diagnosis of volvulus of either the sigmoid or the cecum.

CLINICAL DIAGNOSIS

Volvulus of sigmoid or cecum

DR. BALCH'S DIAGNOSIS

Mesenteric cyst

ANATOMICAL DIAGNOSES

Acute and chronic cholecystitis, with hydrops, producing partial obstruction of cecum
Cholelithiasis

PATHOLOGICAL DISCUSSION

DR. GIDDINGS: At operation the diagnosis was immediately apparent. In the abdomen an enormously distended gall bladder, 18 cm long and 10 to 13 cm in diameter, extending to the crest of the ilium, was found. It was acutely inflamed and markedly thickened, and there was an adhesion between the gall bladder and the cecum, with apparently partial obstruction and distortion of the cecum to produce the x-ray picture. With removal of the gall bladder the cecum fell back to its normal position.

DR. CASTLEMAN: Can the gall bladder be seen on this film?

DR. LINGLEY: The mass described in the record was probably the gall bladder.

DR. CASTLEMAN: Is it not too low?

DR. GIDDINGS: I think that the mass was a little too far forward on the left for the gall bladder.

DR. CASTLEMAN: The gall bladder we received was enormous, it was fully distended, with marked inflammation, both acute and chronic. A stone impacted in the ampulla had caused the marked distention.

CASE 32352

PRESENTATION OF CASE

A seventy-four-year-old housewife entered the hospital because of abdominal pain.

For two years before entry the patient had had intermittent attacks of sharp periumbilical pain.

An operation was performed on the second hospital day

CASE 32352

PRESENTATION OF CASE

A seventy-four-year-old housewife entered the hospital because of abdominal pain.

For two years before entry the patient had had intermittent attacks of sharp periumbilical pain

lasting from several hours to several days. Ten days before entry she began to have a particularly severe attack and vomited some whitish material. Because the pain continued she went to bed, where she remained until admission. Seven days before entry she had had several loose bowel movements, but thereafter the stools were brown and normally formed. On the day of admission the patient felt unusually weak, sweaty and nauseated. She vomited several times, producing some whitish material. The periumbilical pain was also severer but was relieved by codeine. When she was seen that night she had been free of pain for about three hours. There had been no hematemesis, melena, fever, chills or upper respiratory infection.

The appendix and one ovary had been removed at the age of twenty-nine.

Physical examination revealed a poorly nourished woman with cold extremities and livid mottling over the chest and abdomen. The pupils were small and reacted poorly to light. The heart sounds were weak but otherwise of good quality. The heart rate was 96. Fine inspiratory rales were heard at both lung bases. The abdomen was soft and non-tender. Peristalsis was somewhat hyperactive. No masses could be felt. Pelvic examination was negative except for a slight prolapse, with cystocele and rectocele.

The temperature was 99°F, and the respirations 18. The pulse and blood pressure were unobtainable.

Examination of the blood revealed a red-cell count of 6,400,000, with 60 per cent hemoglobin, and a white-cell count of 20,000.

The patient was anuric on admission, and no urine was found in the bladder. A small specimen obtained on the following day gave a + test for albumin, and the sediment contained 5 to 10 white cells per high-power field. A culture grew abundant nonhemolytic streptococci. A glove specimen of stool was guaiac negative.

Soon after entry the patient vomited about 150 cc of dark-red material, which gave a ++++ guaiac test. She was given plasma, 5 per cent dextrose in saline and adrenocortical extract. After about three hours of intravenous therapy the blood pressure was 78 systolic, 0 diastolic. A white-cell count done seven hours after entry was 37,400, with 99 per cent neutrophils, and the red-cell count was 6,870,000. Intravenous and intramuscular penicillin was started. Nevertheless the patient gradually lapsed into coma, from which she could be aroused only by painful stimuli.

On the morning after admission the abdomen was noted to be somewhat distended and doughy. Deep pressure in any quadrant caused the patient to cry out. Below the umbilicus in the midline there was a suggestion of a soft mass that did not pulsate. Peristalsis was less active than previously.

Further blood studies revealed a nonprotein nitrogen of 48 mg per 100 cc and a serum amylase

of 50 units. A lumbar puncture and examination of the spinal fluid were negative. A plain film of the abdomen showed gas-filled, dilated loops of small bowel in the midabdomen, which appeared to be jejunum or upper ileum. There was also a considerable quantity of gas in the transverse colon but little distal to the splenic flexure. The loops of small bowel were spread from one another, suggesting the presence of free fluid. A film of the chest was unsatisfactory because of motion but showed a large area of haziness, homogeneous density at the left base.

Toward evening of the second hospital day respirations became gasping in quality. The abdomen had become resistant and was still tender to palpation. A Miller-Abbott tube drained 500 cc of chocolate-brown, guaiac-positive liquid with a fecal odor. Gradually the patient's breathing became progressively shallower, and the blood pressure again fell, despite continuous intravenous fluids.

The patient expired thirty hours after admission.

DIFFERENTIAL DIAGNOSIS

DR EDWARD HAMLIN, JR. May we see the x-ray films?

DR JAMES R. LINGLEY. These films are of rather poor quality but show gas in both the colon and the small bowel.

DR. HAMLIN. Can the gas in the colon be traced from the cecum?

DR LINGLEY. Only around to the region of the splenic flexure, from there on there is extremely little gas. This film of the chest shows a great deal of motion, but there is definite consolidation of the left base.

DR HAMLIN. The one post-mortem finding that I am sure of is bronchopneumonia, but presumably there was something else.

I have been unable, in reading this abstract, to form any satisfactory diagnosis that fits all the criteria. The impression is given that this type of pain existed intermittently for two years, and it becomes difficult to explain this particular attack, which occurred for ten days but with no great change until the very end. The patient had had several loose bowel movements, but the stools were brown and normally formed. Does that mean that she continued to have bowel movements up to entry? I am trying to find out whether there is any question of intestinal obstruction. The question is raised by the x-ray findings to a certain extent, and there are sufficient other factors to make one think of obstruction, although the history is not particularly suggestive. At entry she was obviously in shock. The description of the abdomen is somewhat difficult to interpret, but I gather that the examination was completely negative. Is that correct?

DR DONALD S. KING. This woman was a patient on the Medical Ward on which I was visiting. I

saw her only once on the morning after she was studied in the Emergency Ward. She had entered the hospital in shock, and had been observed by the physicians on various services, including one of the surgical services. At the time I saw her I was told that examination of the abdomen had been absolutely negative on the night of admission.

DR. HAMLIN: She was also obviously dehydrated.

The next thing that interests me is the fact that guaiac-positive material was found in the vomitus but not in the stools, which again implies some degree of obstruction. The white-cell count, which was remarkably high for a seventy-four-year-old woman, despite dehydration, makes one think of infarction. The record on the next morning gives a good description of general peritonitis.

The serum amylase was taken presumably for the question of pancreatitis. In this hospital the serum amylase of 40 units is roughly the top side of normal, so that a serum amylase of 50 is slightly above normal and not particularly helpful.

In summary, this was a disease of relatively long duration that produced an intra-abdominal catastrophe terminally and that caused shock and presumably peritonitis. One might infer that the patient ruptured a hollow viscus and died with, of course, bronchopneumonia. If these assumptions are correct, it might be well to consider the possible hollow viscus that could perforate. The first thing to think of is the bowel, and that brings up the question whether it was the small or large bowel, there are points that lead one to suspect either. The fact that guaiac-positive material was vomited soon after entry makes one believe that possibly this was a relatively high lesion. On the other hand, there is meager x-ray evidence in that direction, and I am unable to call this purely intestinal obstruction, since a negative abdominal examination is unlikely after ten days of obstruction.

Could the gall bladder have perforated? That would explain the long history. Perforation would also explain many of the features and, particularly if it were associated with pancreatitis, could produce shock, but there is nothing in the history to lead one to think of gall-bladder disease in any form. So for lack of corroborative evidence I drop that possibility, which brings me back to the question of bowel.

The obvious lesions that produce a long history such as this patient had are chronic intussusception and chronic volvulus, but they would produce more evidence of obstruction terminally and it is difficult for me to believe that such obstruction was present. I can think of no tumor of the bowel of long duration that causes such a shock-like picture, particularly if the question of blood within the lumen of the bowel is considered, and I have an idea that something is going to turn up to make me feel

extremely embarrassed. That brings us to what seems to me the most probable disease, which fulfills most of the criteria but still leaves something to be desired, namely, mesenteric thrombosis. How it could have occurred intermittently for two years I cannot explain, nor do I think it did, but it explains the essentially normal abdomen on entry and also the rupture of the bowel, as the terminal event.

DR. J. W. EWELL: I should like to raise the possibility of carcinoma of the bowel, with perforation.

DR. HAMLIN: I tried to bring in tumor of varying sorts, but I find myself unable to explain how a tumor could have caused shock without peritonitis.

DR. KING: That also bothered me. When I saw the patient she was practically unconscious. We went over the list of possible causes of shock supposedly from an abdominal condition, and put mesenteric thrombosis high on the list. My own guess, which was wrong, was acute pancreatitis, but the trouble with that diagnosis was that it did not explain satisfactorily the symptoms of two years' duration. It is true that when I examined the patient I did not believe that the abdomen was normal. There was some distention, and even though she was almost in coma there seemed to be some tenderness.

CLINICAL DIAGNOSIS

Acute pancreatitis

DR. HAMLIN'S DIAGNOSES

Mesenteric thrombosis

Bronchopneumonia

ANATOMICAL DIAGNOSES

Strangulated small intestine due to an adhesive band

Hiatus hernia

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The abdomen contained 500 cc of hemorrhagic fluid, and an adhesive band, about 1 cm thick, extended from the under surface of the laparotomy scar to a loop of terminal ileum about 6 cm proximal to the ileocecal valve. Almost the entire ileum, which was gangrenous, was strangulated by this band.

The lesion in the left lower-lung field was not bronchopneumonia. It was a hiatus hernia containing a part of the stomach and intestines and causing collapse of the left lower lobe.

DR. HAMLIN: This case serves again to point out that intestinal obstruction, even without strangulation, does not always present the classic signs and symptoms.

lasting from several hours to several days. Ten days before entry she began to have a particularly severe attack and vomited some whitish material. Because the pain continued she went to bed, where she remained until admission. Seven days before entry she had had several loose bowel movements, but thereafter the stools were brown and normally formed. On the day of admission the patient felt unusually weak, sweaty and nauseated. She vomited several times, producing some whitish material. The periumbilical pain was also severer but was relieved by codeine. When she was seen that night she had been free of pain for about three hours. There had been no hematemesis, melena, fever, chills or upper respiratory infection.

The appendix and one ovary had been removed at the age of twenty-nine.

Physical examination revealed a poorly nourished woman with cold extremities and livid mottling over the chest and abdomen. The pupils were small and reacted poorly to light. The heart sounds were weak but otherwise of good quality. The heart rate was 96. Fine inspiratory rales were heard at both lung bases. The abdomen was soft and nontender. Peristalsis was somewhat hyperactive. No masses could be felt. Pelvic examination was negative except for a slight prolapse, with cystocele and rectocele.

The temperature was 99°F, and the respirations 18. The pulse and blood pressure were unobtainable.

Examination of the blood revealed a red-cell count of 6,400,000, with 60 per cent hemoglobin, and a white-cell count of 20,000.

The patient was anuric on admission, and no urine was found in the bladder. A small specimen obtained on the following day gave a + test for albumin, and the sediment contained 5 to 10 white cells per high-power field. A culture grew abundant nonhemolytic streptococci. A glove specimen of stool was guaiac negative.

Soon after entry the patient vomited about 150 cc of dark-red material, which gave a ++++ guaiac test. She was given plasma, 5 per cent dextrose in saline and adrenocortical extract. After about three hours of intravenous therapy the blood pressure was 78 systolic, 0 diastolic. A white-cell count done seven hours after entry was 37,400, with 99 per cent neutrophils, and the red-cell count was 6,870,000. Intravenous and intramuscular penicillin was started. Nevertheless the patient gradually lapsed into coma, from which she could be aroused only by painful stimuli.

On the morning after admission the abdomen was noted to be somewhat distended and doughy. Deep pressure in any quadrant caused the patient to cry out. Below the umbilicus in the midline there was a suggestion of a soft mass that did not pulsate. Peristalsis was less active than previously.

Further blood studies revealed a nonprotein nitrogen of 48 mg per 100 cc and a serum amylase

of 50 units. A lumbar puncture and examination of the spinal fluid were negative. A plain film of the abdomen showed gas-filled, dilated loops of small bowel in the midabdomen, which appeared to be jejunum or upper ileum. There was also a considerable quantity of gas in the transverse colon but little distal to the splenic flexure. The loops of small bowel were spread from one another, suggesting the presence of free fluid. A film of the chest was unsatisfactory because of motion but showed a large area of hazv, homogeneous density at the left base.

Toward evening of the second hospital day respirations became gasping in quality. The abdomen had become resistant and was still tender to palpation. A Miller-Abbott tube drained 500 cc of chocolate-brown, guaiac-positive liquid with a fecal odor. Gradually the patient's breathing became progressively shallower, and the blood pressure again fell, despite continuous intravenous fluids.

The patient expired thirty hours after admission.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD HAMLIN, JR. May we see the x-ray films?

DR. JAMES R. LINGLEY. These films are of rather poor quality but show gas in both the colon and the small bowel.

DR. HAMLIN. Can the gas in the colon be traced from the cecum?

DR. LINGLEY. Only around to the region of the splenic flexure, from there on there is extremely little gas. This film of the chest shows a great deal of motion, but there is definite consolidation of the left base.

DR. HAMLIN. The one post-mortem finding that I am sure of is bronchopneumonia, but presumably there was something else.

I have been unable, in reading this abstract, to form any satisfactory diagnosis that fits all the criteria. The impression is given that this type of pain existed intermittently for two years, and it becomes difficult to explain this particular attack, which occurred for ten days but with no great change until the very end. The patient had had several loose bowel movements, but the stools were brown and normally formed. Does that mean that she continued to have bowel movements up to entry? I am trying to find out whether there is any question of intestinal obstruction. The question is raised by the x-ray findings to a certain extent, and there are sufficient other factors to make one think of obstruction, although the history is not particularly suggestive. At entry she was obviously in shock. The description of the abdomen is somewhat difficult to interpret, but I gather that the examination was completely negative. Is that correct?

DR. DONALD S. KING. This woman was a patient on the Medical Ward on which I was visiting. I

BE NOT THE FIRST

THE physician who has under his care a patient
with Hodgkin's disease, leukemia or some allied dis-
order is not infrequently confronted with the diffi-
cult task of persuading the family, in its despera-
tion, not to cast about for some alleged cure of the
disease rather than to adhere to the more conven-
tional forms of therapy proved by experience to be
beneficial This desire on the part of the family is
easy to understand, for, on the one hand, the phy-
sician in charge must, of necessity, point out the
almost certain fatal outcome, and on the other, the
layman is quick to grasp at straws and all too ready
to believe rumors of true cures by some new and
mysterious substance This is particularly true
when the patient has relatives who are scientists
yet not physicians The situation is made even
more difficult when the lay press publishes premature
and distorted accounts of purely experimental
measures or when a physician, in an unguarded
moment, speaks of a cure when, in actuality, he is
referring to a therapeutic measure under trial that,
at the moment, appears to offer some promise

Twice within the past year the writer of this
editorial has been told by medical students that a
cure for one or another of these malignant or pseudo-
malignant conditions has been found Similar word
has also come to the ears of families some member
of which has been stricken with one of these dread
diseases Thus is false hope raised that serves only
to heighten the distress when failure eventually be-
comes apparent It is probably safe to say that any
doctor thoroughly familiar with these conditions is
aware of what experimental work is being carried
out, and it is also probably safe to say that once a
true cure has been found or a real therapeutic ad-
vance has been made by competent observers this
knowledge will not be long in reaching those in-
terested in the field and, indeed, the medical public
at large Concise official statements from com-
petent investigators may be expected as soon as
they are justified

Such a statement has recently been made by
Rhoads¹ regarding the use of the nitrogen mustards
in leukemia, Hodgkin's disease and certain types of
cancer From this report it is clear that both the
"bis" and the "tris" compounds have definite thera-
peutic limitations and that, broadly speaking, these
substances do not constitute a cure or even a great
advance over the more conventional x-ray treat-
ment Toxic effects, including leukopenia, anemia and
bleeding tendencies, were encountered, and in some
cases the hematopoietic injury exceeded the effect on
the tumor Such remissions as were achieved seldom
lasted more than several months Lymphosarcoma
did not respond to these agents any better than it
does to x-ray, and acute leukemia was not bene-
fited It is stated that chronic leukemia is still
best handled by appropriate radiation, and early,
localized tumors, by radical excision or local radia-
tion It is concluded that "the experimental use of
the nitrogen mustards in the treatment of any active,
extensive, neoplastic process is probably justified
if other methods of control have proved to be with-
out benefit "

In a somewhat similar vein there is a report from
England on the use of urethane in leukemia² Thirty-
two cases were treated, and in most there was a
marked drop in the white-cell count, a reversal of
the differential to more nearly normal and a rise of
the red-cell count, but again the beneficial results
were temporary and there were toxic manifestations
The authors conclude that there is "no indication
that permanent benefit may result from the use of
urethane in either myeloid or lymphatic leukemia "

These reports are not encouraging, but they are
extremely valuable, since they place in the hands of
the attending physician the knowledge that the
conventional form of therapy, whether it be radiation
or surgery or both, is still best in the hands of com-
petent men, and since they form a firm basis on
which to base a reluctance or even a refusal to per-
mit such therapeutic measures to be used in the
average case of neoplastic or pseudoneoplastic
disease

POSTWAR WORLD

THE postwar world, to date, has been a world of mutual distrust, jealousy and suspicion. It has been a world of unrest, of strife, of disharmony, of violence, of muscle-bulging. We are learning again, as we have learned before and forgotten, that alliance in a common cause does not mean even temporary friendship. The emotional factor of good will is a personal, not a group, phenomenon, and rarely is the moral discipline of the individual sufficient to place good will above immediate self-interest.

The Four Freedoms, around which the allied nations rallied in the dark war days, have been kicked into a cocked hat by some of their adherents and allowed to remain there by the rest. Poland is again bringing to perfection her peculiar art of the pogrom

Mikhailovitch, whom many still suspect of having been one of Yugoslavia's great patriots, has been eliminated by due process of postwar law, on the other hand Bolivia's dictator, after a man hunt through his palace, was recently liquidated and hanged *in corpore delicti*.

Palestine, which gave us one of our early examples of man's violent reactions to a policy of good will toward man, still furnishes us with illustrations of violent reactions. Trieste, that gem of the Adriatic, is again the victim of a snatching contest. China is being spun like a top by her various factions, and Madame Sun Yat-sen, perhaps with some justice, wants the Americans out. Manchuria has apparently been thoroughly looted by our hearty former co-belligerents, the genial Russians, of whom it is currently said, however, that the marshals who won the war are being looked on coldly by the big boss.

Nature has done her best to add to mankind's confusion by providing two years of almost unprecedented crop failures over much of the world, and economic unrest at home seems to be accompanied by that strawberry shortcake of modern journalism—an outbreak of private slaughter, mayhem and rape. Congress, moreover, according to present indications, seems of a mind to preserve the Nation's health by right of eminent domain.

Our domestic problems we will no doubt stagger along with and settle in the usual bivalent democratic fashion—partly right and partly wrong. So far as our foreign relations are concerned, Brooks Atkinson, the able *New York Times* correspondent recently returned from Russia, has given probably the best picture of the working policy toward its neighbors of the bear that walks erect. It might be phrased in the words of the mate of the whaler *Mozambique* to his skipper: "All I wants from you is ceevility and d— little of that!"

We now know that Russia is bent on fulfilling her own destiny and believes that destiny to be incompatible with the rights of other nations. Her government has not learned—perhaps cannot learn—the lesson of compromise and cannot understand that various political ideologies may exist side by side in the same world. Much may be expected eventually of the Russian people, when

the body only which is out of health, but always the complete being." Often the reasons for leaving the hospital are obscure and great skill is needed to help the patient to be realistic and to direct himself toward the goal of complete recovery.

The treatment and hospitalization of patients with tuberculosis involves months or years of restricted activity. A young athletic boy, suddenly faced with tuberculosis, may revolt at accepting this state. Since the tubercle bacilli carry on their destructive work insidiously, the patient, after he has regained some strength, will insist that his cure is completed. This view is maintained despite the contrary evidence of x-ray and sputum reports. Perhaps the fear of the disease is so great as to cause the patient to reject its reality.

The older man and woman, accustomed to years of labor in factory and home, may also find it difficult to accept the new role of inactivity and dependency. Experience has not fitted them to fill the passing empty hours. The thought of lying quietly in bed while the world hurries on is untenable, and they are tortured by the desire to be back among the working multitudes.

This boredom is more readily conquered by patients accustomed to study or reading, or those who are fortunate enough to have a hobby. Hospitalization is a difficult experience for the majority, but it can be a constructive one. Rarely does a patient who has found activities that lead to growth and development, sign out against advice. There is also a distinct difference between those patients who have made their adjustment and those who have succumbed to the sheltered life of the hospital and have regressed to an infantile, dependent level.

There does not appear to be any constant point at which a patient may feel that the hospital is no longer bearable. Even when he may be apparently adjusted to the hospital routine, the inactivity may lead to cumulative effects until a breaking point is reached. A little supportive treatment at this time will often tide the patient over the rough spot.

A patient entering a hospital brings with him the sum total of his life experiences. He has certain ties, certain obligations, and these remain though they are altered by the new experience. Early contact with the patient and his family can give clues to the patient's motivations and the part the family will play. The marital strengths, the interfamily ties and strains, the relationship in a changing setting should all be weighed and evaluated with the patient. The patient must, if possible, be spared the worry and anxiety of the family. This cannot be done by simply hiding or ignoring real problems. If the family is aware of this, they can show the patient their strengths in meeting problems and assure him that they can keep their balance.

The social worker is often faced with a recently admitted patient who demands to leave the hospital with or without the doctor's permission. An interview usually begins with the patient demanding, "How can I remain here while my family starves?" The social worker can be of invaluable aid in directing the family to sources of help and thus make it possible for the patient to accept his hospital stay knowing that his family will not starve or go homeless.

Life in a hospital is complex. A patient is faced with the need to adjust to his companions, the doctors, the nurses and other personnel. He has to give up practically all his privacy, both physical and mental. There are new ideas to be adjusted to in this microcosm of all nations and races. It is not difficult for friction to arise between the patient and a particular person or routine. Personalities may clash and the sick person may feel that the only solution lies in leaving the hospital. Sometimes the patient does not indicate the real reason for signing out but gives the usual statement that he "can do just as well at home." Other patients are quite verbose regarding the sources of annoyance.

All members of the hospital team can play very important parts in helping the patient adjust not only to his illness but to the hospital life. A healthy adjustment in the hospital implies a psychologic awareness and acceptance of the illness. When the acceptance has not been achieved, the patient rejects the hospital as a symbol of the disease. In the adjustment of the patient to the hospital one factor that might be given special attention is the food. Tuberculous patients are very conscious of the role of food in their cure and of the variations in their weight. This is one of the chief topics of conversation. One director of a sanatorium when asked how he kept down his A O R discharges to a surprisingly low figure

replied that he gave the patients the type of food they would get in their own homes.

An analysis cannot give all the reasons why patients interrupt the treatment process. The individuality of every situation is marked, and therein lies the challenge. The problem is a big one. There has been a constant war against tuberculosis. In its earlier stages this fight was on a mechanical level of cleaning up slums, taking mass x-rays or providing the proper type of hospital care. But now we have come to realize that we are dealing with human beings and the control of the disease will come only when the sick person is prepared to participate. — Reprinted from *Tuberculosis Abstracts*, August, 1946

CORRESPONDENCE

CESAREAN SECTION VERSUS TEST OF LABOR

To the Editor: In his paper appearing in the June 27 issue of the *Journal Dr Waters*, in discussing fetopelvic disproportion in the borderline pelvis, states "We frankly admit our inability in many such cases to decide in advance of an adequate test of labor the ability of the patient to deliver herself or to be safely delivered by vagina. We marvel at the judgment and experience of the omniscient, which permit in advance of labor appreciation of the size, shape and moldability of the fetal head, the extent of the physiological relaxation of the pelvic joints, the thickness and tension of the nonosseous pelvic structures, the character and effectiveness of the uterine contractions, the time factor in even partial dilatation and effacement of the cervix." This represents at once an admirable candor and a great waste of wonder. It poses numerous questions.

What is obvious fetopelvic disproportion? Is it invariably concomitant with contracted pelvis borderline or otherwise? What is an "adequate test of labor"? Who are those who possess such judgment and experience that in advance of labor they appreciate the factors listed by Dr Waters? Where does he find the names or writings of those termed "omniscient"? When and where have they stated that they possess in advance of labor the fundamental obstetric information suggested by Dr Waters? Will he tear away the veil of anonymity?

It is no omniscience which we bring to our opposition to test or trial of labor. It is rather a profoundly felt resentment of our own ignorance coupled with the fact that we have learned that an adequate test of labor is no cheap commodity. It has no fixed or predictable price. All too often obstetricians are faced with the problem posed by Dr Waters. All too often, despite all available data, including accurate clinical and x-ray mensuration and the excellent procedure of Hillis, we do not know in advance of labor whether or not the presenting vertex will enter the pelvis. Faced with our own ignorance we have available for the solution of the problem two procedures each necessarily a mere reflection of that ignorance. One may proceed to elective section or to adequate test of labor. Our choice is elective section because we know what it costs.

What is the price of section? The mortality for elective section of the lower segment type is 0.5 per cent.

What exacton is made for a test of labor? Perhaps none. Perhaps twenty-four to ninety-six hours of irregular, purposeless, inefficient pain with the patient undelivered, exhausted and infected at the end of such time — a major surgical risk. Perhaps a long labor with a badly battered or dead baby as a reward. Perhaps a long labor terminated by a technically and physically difficult instrumental delivery with injury or death to the baby and the mother left with a vesical or rectal fistula or a permanently relaxed or damaged pelvic floor. Perhaps death. There is no fixed or predictable price.

In the day when mortality following section was 50 per cent test of labor was mandatory and section barely thinkable. That day passed in 1882. Test of labor should have passed with it. It properly belongs with the thinking of 1882.

There is no omniscience in electing section. There is knowledge of the cost and knowledge of the outcome. Section electively performed carries a mortality of 0.5 per cent, and section thus performed will increase section incidence by 1.5 to 2.0 per cent.

In the matter of management of the patients exhibiting eclampsia, Dr Waters states, "We do not perform cesarean

DEATHS

BUSSEY — Floyd H. Bussey, M.D., of New Bedford, died May 1. He was in his sixty-second year.

Dr. Bussey received his degree from the University of Michigan Homeopathic Medical School in 1910. He was a fellow of the American Medical Association.

COLLINS — Richard Collins, M.D., of Waltham, died July 28. He was in his seventy-second year.

Dr. Collins received his degree from Harvard Medical School in 1900. He was a member of the staff of the Waltham Hospital, a member of the American College of Surgeons and a fellow of the American Medical Association.

His widow, a son and a daughter survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

POSTPONEMENT OF ELECTIVE TONSILLECTOMY

The Department of Public Health again feels it necessary to advise against elective tonsillectomy during the poliomyelitis season. This constitutes one of the few effective measures that can be taken to minimize the serious effects of poliomyelitis. Although the incidence of the disease is not so high this summer as it was last year, cases are occurring regularly and it is significant that a history of antecedent tonsillectomy was given in three cases, two of which had bulbar paralysis.

†Four-year average.

COMMENT

Diseases reported at an incidence above the seven-year median included chicken pox, German measles, measles, typhoid fever and whooping cough.

Although anterior poliomyelitis was reported at a figure above the median prevalence, there is no evidence at present that this disease will reach epidemic proportions this year.

Diphtheria was reported at the highest figure for the month of July in the past ten years. This was also true for the months of May and June.

Diseases reported below the median prevalence included bacillary dysentery, meningococcal meningitis, mumps and scarlet fever.

Lobar pneumonia was again at a record low for the sixth consecutive month.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from Arlington, 2; Boston, 1; Cambridge, 1; Falmouth, 1; Marblehead, 1; Medford, 1; Washington, 4, total, 11.

Diphtheria was reported from Boston, 6; Cambridge, 1; Chelmsford, 1; Everett, 1; Framingham, 2; Gloucester, 1; Lowell, 2; Lynn, 1; Newton, 2; Somerville, 2; Taunton, 6; Worcester, 3, total, 34.

Dysentery, bacillary, was reported from Boston, 1; Worcester, 4, total, 5.

Encephalitis, infectious, was reported from Southbridge, 1, total, 1.

Malaria was reported from Arlington, 1; Attleboro, 1; Boston, 14; Bourne, 1; Cambridge, 2; Georgetown, 1; Haverhill, 2; Hingham, 1; Longmeadow, 1; Lynn, 2; Medford, 1; Newton, 1; North Andover, 1; Peabody, 1; Rockport, 1; Salem, 1; Shrewsbury, 1; Townsend, 1; Waltham, 1; Winchester, 1; Worcester, 3, total, 39.

Meningitis, meningococcal, was reported from Boston, 2; Fitchburg, 1; Holyoke, 1, total, 4.

Meningitis, Pfeiffer bacillus, was reported from Boston, 2, total, 2.

Meningitis, pneumococcal, was reported from Amherst, 1; Belmont, 1; Boston, 3; Fitchburg, 1; Malden, 1, total, 7.

Meningitis, undetermined, was reported from Brookline, 2; Cambridge, 1; Millbury, 1; Newton, 1; Plymouth, 1; Worcester, 1, total, 7.

Salmonella infections were reported from Belmont, 1; Bernardston, 1; Boylston, 1; Cambridge, 1; Falmouth, 1; Lawrence, 2; Lowell, 1; Newburyport, 1; Newton, 1; Northampton, 1; Templeton, 1; Waltham, 1; Worcester, 1, total, 14.

Septic sore throat was reported from Boston, 5; Foxboro, 1; Greenfield, 1; Quincy, 1, total, 8.

Trichinosis was reported from Boston, 1; Cambridge, 2, total, 3.

Typhoid fever was reported from Andover, 1; Arlington, 1; Boston, 1; Chelsea, 1; Somerville, 1; Springfield, 1; Worcester, 1, total, 7.

MISCELLANY

THE SIGNING OUT OF TUBERCULOUS PATIENTS

When the private physician makes a diagnosis of tuberculosis and succeeds in getting a patient under sanatorium care, he is apt to feel that his job is done. If that patient leaves the sanatorium prematurely, his physician will be handicapped in his subsequent efforts by the failure of this first hospital experience. A knowledge of some of the factors that lead tuberculous patients to leave hospitals against medical advice should help physicians to prepare patients for accepting and completing hospital care. The matter is discussed in a paper, "The Signing Out of Tuberculous Patients," by Jean Berman and Leo H. Berman, which appeared in the April, 1944, issue of *The Family*.

Those who are interested in helping a patient to use the medical care necessary for recovery and to accept a possible physical limitation, find challenging problems in work with the tuberculous. The importance of this may be realized when hospitals in different parts of the country report that from 22 to 65 per cent of their patients leave A. O. R. ("at own risk").

The patients who refuse all treatment have not been considered. The focus has been on patients who have evinced a desire to get well but who during the course of treatment attempted to terminate their recovery process. All hospital personnel, including the social worker, must accept "It is never

PULMONARY TUBERCULOSIS IN HARVARD MEDICAL STUDENTS*

HENRY P. BREAN, M.D.,† AND LEWIS W. KANE, M.D.‡

BOSTON

DESPITE the marked fall in recent years in the morbidity and mortality due to pulmonary tuberculosis and despite advances in its early diagnosis and treatment, tuberculous infection of the lung remains the most serious medical problem that confronts the medical student. Although for more than a century European clinicians had been aware of an apparent high incidence of pulmonary tuberculosis among medical students, it was not until 1930 that Steidl¹ called to the attention of American clinicians the fact that a similar high incidence was being overlooked in American medical schools. Stimulated by Steidl's report, Hetherington and his co-workers² conducted a survey showing that over 20 per cent of the senior class at the University of Pennsylvania Medical School had what they considered to be significant adult-type pulmonary tuberculosis. This alarming report stimulated the undertaking of surveys at other medical schools. In 1939 Soper and Amberson³ reviewed information collected from surveys made at the medical schools of the universities of Pennsylvania, Wisconsin and Oslo and of Johns Hopkins, Yale, Columbia, Harvard, Stanford and New York universities and at the Woman's Medical College. The incidence reported from these schools varied from 0.4 per cent (Columbia) to 13.5 per cent (University of Pennsylvania). Since Soper and Amberson's report surveys have been conducted at Cornell⁴, Northwestern⁵ and New York universities.⁶

As might be expected, there was significant variation in the rates at various schools, depending on the geographical origin of the student body, the location of the school, the diagnostic criteria and the care with which the survey was conducted.

*From the Department of Radiology, Peter Bent Brigham Hospital, the Department of Hygiene, Harvard University, the Medical Clinic, Peter Bent Brigham Hospital, and the Department of Medicine and the Department of Bacteriology and Immunology, Harvard Medical School.

†Junior associate in radiology, Peter Bent Brigham, New England Deaconess and Children's hospitals; formerly, assistant resident physician, Peter Bent Brigham Hospital.

‡Assistant in bacteriology and immunology, Harvard Medical School; assistant in medicine, Massachusetts General Hospital; formerly physician, Department of Hygiene, Harvard University.

Many schools, particularly in the early reports, found that the previously known incidence tripled or quadrupled when formal case-detecting programs were instituted. Other factors, such as the irregular occurrence of epidemics of tuberculosis in certain highly susceptible or heavily exposed classes, occasionally operated to produce unduly high figures. Furthermore, some of the high incidences reported in the earlier papers appear to be partly based on the presence of lesions that would now be considered obsolete tuberculosis of no clinical importance. It was presumably a combination of many such factors that produced the uniquely high figures at the University of Pennsylvania—a rate rarely even approached in the experience of other schools. Most carefully conducted surveys report an incidence in the neighborhood of 1 or 2 per cent.

In the light of present knowledge, it is the purpose of this paper to review and analyze the material on pulmonary tuberculosis that has accumulated in the records of the health office at Harvard Medical School during the last twenty-three years. In so doing an endeavor will be made to trace the steps that led to the evolution of the case-finding program now employed at Harvard Medical School.

MATERIAL AND METHODS

The data presented in this study were obtained chiefly from a search of the records kept by the physicians to students at Harvard Medical School. The medical histories of twenty-four classes, beginning with the class of 1926, were studied. All available clinical information in the files of the Health Office, as well as sanatorium reports and personal communications, was reviewed in each case. The x-ray films available in 23 cases were reviewed, with special attention to the extent and location of the lesions.

In all cases presented in this study chest films showed either the appearance of a lesion not previously present or extension of a previously known

§These records were kept by Drs. Reginald Fitz, Clark Heath, Eugene Eppinger, Lewis Dexter and Lewis Kane.

section on patients with eclampsia unless antitoxic measures have checked the eclampsia and made the patient operable." Now how is it known that the "antitoxic measures" have checked the eclampsia? How is it known that the patient has been made "operable"? What are the measures which have such virtue? If a convulsion is stopped medically has the eclampsia ceased? If measures stop convulsions, how predict the time at which the next will arrive? How long does Dr. Waters wait after eclampsia is checked before he operates? What criteria does he use to determine the operability of the patient?

Dr. Waters is to be congratulated on the excellent record of his clinic. His paper is of great value and certainly contains a wealth of provocative and stimulating matter.

MILTON J. SCHREIBER, M.D.

320 Central Park West

* * *

Dr. Schreiber's letter was referred to Dr. Waters, whose reply is as follows:

August 6, 1946

To the Editor: The wording of the referred-to paragraph is sufficiently explicit, I trust, even to the omniscient, to clarify our attitude with respect to test of labor. Dr. Schreiber determines *in advance of labor*, after considering "all available data including accurate clinical and x-ray mensuration and the excellent procedure of Hillis" whether or not a patient requires a cesarean section. Since none of us may possess the fundamental obstetric data which I referred to but which all of us, including Dr. Schreiber, must at least consider, it is clear that he qualifies most excellently as one of the "omniscient" and can find his companions in the literature with no help from me.

The picture Dr. Schreiber paints of the patient who has been given a test of labor is harrowing and pitiful, even though nonexistent, at least in our clinic. With adequate analgesia, supportive ante-partum therapy and careful labor observation, there is no reason why such patients should be exhausted, dehydrated, infected or poor surgical risks. If a gross error of judgment is made, which on occasion seems well within our experience, there are suitable operative procedures which minimize the risk and approximate the mortality given by Dr. Schreiber for purely elective section.

In my own private service I have had no maternal cesarean death in more than fifteen years following any type of cesarean operation. With rare exceptions, I invariably allow primiparas enough labor to demonstrate the effectiveness of the normal mechanism, and if the hours of labor and ruptured membranes exceed our safety period, I resort to extra-peritoneal section—which even then is as safe as the elective operation. To me, a test of labor so conducted is a cheaper "commodity" than increasing the general cesarean incidence by 1.5 to 2.0 per cent, and I question the quoted 0.5 per cent mortality for elective cesarean section if applied to the country at large.

I trust those who read Dr. Schreiber's letter will also read my article and study the tabular data given on eclampsia, which should satisfy the questions asked. Most patients who have eclampsia will deliver vaginally. But an independent indication for section may be present, or the patient may fail to maintain improvement after a seeming happy response to initial therapy. Cessation of convulsions, recovery from coma and stupor, clearing of the pulmonary passages, lowering of blood pressure and pulse rate, and restored urinary output will serve notice that operation may be assayed under spinal anesthesia in the needed case, but with an accepted risk by virtue of the eclamptogenic toxemia itself. Experience with enough clinic and post-mortem material teaches that no didactic answers may be made to Dr. Schreiber's questions on eclampsia. We are guided to such answers by the considered results of experience over years as applied to each eclamptic patient, and the efficacy of our scientific guessing or balanced judgment as you will may be determined from the data I submitted. That, I believe, speaks sufficiently well for itself.

BOOK REVIEW

A Manual of Surgical Anatomy By Tom Jones and W. C. Shepard. Prepared under the auspices of the Committee on Surgery, Division of Medical Sciences, National Research Council. 4th ed., cloth, 195 pp., illustrated. Philadelphia and London: W. B. Saunders Company, 1945. \$5.00.

This excellent manual measures up to the high purpose for which it was developed. In the words of Major General Norman T. Kirk, the surgeon general of the Army, the aim of the manual is "to provide a concise atlas of applied surgical anatomy which permits rapid visual review of any part of the body and the proper surgical approaches to the various regions to the surgeon who may be called upon to perform urgent surgical procedures on the wounded." The drawings, arranged regionally, are from the skillful hands of the expert artists Jones and Shepard. The illustrations are simple line drawings, with the names placed on the various structures themselves. Inasmuch as good surgery depends, to a large extent, on thorough familiarity with the anatomy and structural relation of the parts involved, a careful thoughtful study of the illustrations will serve the best interests of the surgeon. There is a useful fifty-four-page explanatory index. The text is divided into four parts: head and neck, trunk-thorax, abdomen and pelvis, upper extremity, and lower extremity. This book makes a definite contribution to medical and surgical thought and merits a wide reception.

NOTICES

DIABETES CLINIC

Eli Lilly and Company will sponsor a diabetic clinic to be held at the Indiana University Medical Center in Herty Hall of the State Board of Health Building, Indianapolis, Indiana, on September 23—a week following a program at the University of Toronto in honor of the twenty-fifth anniversary of the discovery of insulin. International importance will be given to this meeting by the presence of Professor Charles H. Best, of Toronto, Canada, Professor Bernardo A. Houssay, of Buenos Aires, Argentina, Dr. R. O. Lawrence, of London, England, and Dr. H. C. Hagedorn, of Gentofte, Denmark. Various phases of diabetic care will be discussed.

(Notices continued on page 3111)

The demonstration of an incidence almost three times that known before the introduction of a case-finding program is in accord with the experience of other medical schools. At the universities of Minnesota,¹¹ Wisconsin¹² and Pennsylvania² and at Yale University¹³ the introduction of case-finding programs increased the previously known rate between four and six times.

Development of Tuberculosis according to Academic Year

The academic year in which the lesion was first discovered is known in 34 of the 44 cases and is listed in Table 2. The fourfold increase in the

number of cases appearing in the last two academic years, as compared with the first two, is discussed below. A similar finding has been reported from other medical schools.^{2, 5, 6, 14}

Significance of Tuberculin Reaction

The tuberculin reaction on entrance to medical school was known in 26 cases prior to the development of the pulmonary lesion. Sixteen students were positive reactors, and 10 were nonreactors. Of the former, 3 were found to have active lesions on x-ray examination at entrance, 13 positive reactors and 10 nonreactors developed lesions during medical school. Since Classes 1936 to 1948 included 51.7 per cent positive reactors and 48.3 per cent nonreactors on entrance, the ratio of 13 positive reactors to 10 nonreactors suggests that the nature of the tuberculin reaction on entry had little influence on the development of active pulmonary tuberculosis in medical school.

On the other hand, conversion from nonreactive to reactive state while in medical school carried a definite liability. In Classes 1936 to 1947 there were 188 students who were nonreactors on entrance but who subsequently became reactors while in medical school. Of these, 10 (5.3 per cent) developed active pulmonary tuberculosis in medical school, and at least 3 others developed parenchymal or pleural tuberculosis soon after graduation. Information on the status of the remainder of the group after graduation is too fragmentary to permit estimation of a postgraduate incidence.

Three students who developed clinical pulmonary tuberculosis were known to have been nonreactors five, eleven and eleven months before the diagnosis was established. The importance of this fact in determining the proper timing of the interval when routine x-ray examination or tuberculin tests should be performed is discussed below.

No case of pulmonary tuberculosis was found in any student with a negative tuberculin reaction. The number of positive reactors, if any, who became nonreactors during medical school is unknown, since positive reactors were not retested. In non-medical groups it has been shown that a small but significant number of reactors lose their reactive state during varying periods of observation.^{15, 16}

Classification of Pulmonary Lesions

The extent and intensity of the pulmonary lesions were classifiable in 26 of the 31 cases in classes 1936 to 1948. On the basis of the National Tuberculosis Association criteria,¹⁰ 18 were minimal lesions, and 8 were moderately advanced. Cavitation was rare, being demonstrable in only 3 cases.

Since most of the lesions were minimal all were subgrouped according to the classification of Sampson¹⁷ in use at the Trudeau Sanatorium, which is based on intensity (chiefly density) of the lesion, as well as on its area. Intensity A is slight, B is

moderate, and C represents consolidation, cavity or dense fibrosis. Any of these intensities may be applied to a minimal, moderately advanced or far advanced lesion. When the 26 cases were so reclassified, 13 appeared as minimal of A intensity and constituted the minor-lesion group. Thirteen others appeared as minimal of B or C intensity or as moderately advanced of A, B or C intensity, constituting the major-lesion group. Pleural effusions were classified as major lesions.

Confirming the validity and prognostic value of this grouping was the marked difference in degree and duration of disability between the categories. Of the 13 cases comprising the minor-lesion group, 7 students did not require sanatorium care. For the 6 requiring sanatorium care, the period of hospitalization varied from ten to twenty months, with an average of fourteen months. Two of these

lesion. Calcified primary complexes, however extensive, thickened apical caps, blunted costophrenic angles and small apparently obsolete nodules were not considered clinically significant, and are not included in any of the tabulations or discussions. Supporting clinical evidence for activity included at least one of the following characteristic symptoms: cough, hemoptysis, fever, anorexia, weight loss and general malaise. In many cases acid-fast bacilli were demonstrated in the sputums, gastric washings or pleural effusions, either by direct observation or by guinea-pig inoculation.

The tuberculin-test figures were derived from the original work sheets of the routine tuberculin surveys. The two-test-dose, intradermal method was used, the results being read in forty-eight hours. Induration of at least 5 mm in diameter was used as the sole criterion of a positive test. No student was considered a nonreactor unless the full strength of the second dose — 10 mg O T (Old Tuberculin) or 0.005 mg P P D (Purified Protein Derivative) — had been given. Classes 1936 through 1940 and the Class of 1941 during its first three years were tested with O T, all subsequent classes were tested with P P D.

From 1922, when records were first kept, until 1932 no routine case-detection program was employed. In the latter part of this period, however, more than four hundred chest x-ray films were taken on the basis of weight loss, history of contact, suggestive symptoms or suspicious signs.⁷ The first routine case-detection program, which was adopted in 1932, consisted of intradermal tuberculin tests and x-ray examination of the chest for all members of the entering classes and also for many members of the graduating classes. In 1936 the plan was extended to include annual tuberculin retesting of all nonreactors, and all positive reactors were encouraged to have annual x-ray examinations of the chest.⁸ The present method was adopted in 1943, although it did not have complete application until 1944. Routine tuberculin tests and x-ray examinations of the chest were done on all members of the entering classes. The students were then re-examined semiannually — tuberculin reactors by x-ray and nonreactors with tuberculin. Although the semiannual rule was not effectively enforced until 1944, its official adoption in the preceding year led to virtually complete participation of the student body in at least one routine examination in that year, participation had previously been wide but not complete.

RESULTS

X-ray Findings

From 1922 through 1945, a total of 44 students were known to have developed active pulmonary tuberculosis on the basis of the criteria outlined above. The x-ray films were available for study in

23 cases, in the remainder the information was gleaned from the reports of the radiologist.* Most of the lesions were in the apical or subclavicular areas. A characteristic position was the outer portion of the second anterior interspace, as pointed out by Sosman.⁹ About 70 per cent were minimal (National Tuberculosis Association classification¹⁰), and the remainder moderately advanced. There were no known far advanced lesions in the initial x-ray films. Demonstrable cavitation was rare, occurring in only 3 cases. Four cases that developed in medical school and had apparently inactive lesions in the x-ray films on admission are included in this study because none of the lesions appeared to be a direct recurrence of a previous one. In 2 cases of massive pleural effusion without demonstrable parenchymal involvement, acid-fast organisms were demonstrable in the pleural fluid.

Incidence

Of 3160 students in Classes 1926 to 1948, it is known that 44 developed pulmonary tuberculosis — an over-all incidence of 1.4 per cent. Because of the relative inefficiency of the case-finding program prior to 1936, however, the actual rate of the disease was undoubtedly considerably greater. Thus Classes 1926 to 1932, in which no organized case-finding program was conducted, had an incidence of 0.9 per cent. Classes 1933 to 1936 had routine chest films and tuberculin tests on admission, and many, but not all, students had chest films in their fourth year, in this group the incidence was 1.1 per cent. These figures may be contrasted with those for Classes 1937 to 1943, in which routine chest x-ray examination and tuberculin tests on admission were followed by annual re-examination of all nonreactors by the tuberculin test and of

in tuberculosis in the general population. A similar decreasing incidence of positive reactors during approximately the same period has been noted among students entering college¹⁹ and other medical schools.¹⁴

The rate of conversion of nonreactors to reactors while in medical school is shown in Table 9. Except for the third-year and fourth-year tests on Classes

lesions have had prolonged periods of disability, averaging over two and a half years of absence from medical school. In addition, several failed to complete their medical education. Almost without exception, students whose lesions were detected by the appearance of symptoms showed major lesions, whereas just as regularly students whose lesions were detected by routine examination showed minor lesions. Only about half the students with minor lesions required sanatorium care. The average stay of those who required such care was fourteen months.

The demonstrable effectiveness of routine examination in the detection of early lesions makes frequent examination mandatory. The original case-finding program at Harvard Medical School, consisting of routine tuberculin tests and chest x-ray examination on entry and at graduation, has been progressively modified to the present semi-annual examination. During the period of annual examination one of us (H P B²⁰) was able to show, on the basis of the existing Harvard Medical School material, that when routine chest x-ray examinations were done only annually or approximately annually, a large proportion of the lesions became symptomatic, and were thereby detected, before the time of re-examination. In addition, at least 3 students developed major lesions within a year of having been found to be nonreactors in the annual test.

Since major lesions often develop within a year after infection or after a negative chest x-ray examination, it is our belief that six months repre-

sents the maximum interval that should be allowed to elapse between routine x-ray examination of tuberculin reactors and tuberculin tests of non-reactors. When students previously nonreactors become reactors in the semiannual examination, x-ray examination of the chest should probably be done every six weeks for six months, and every three months for the remainder of the year. The use of this case-finding routine examination has, so far, eliminated the previously preponderant major

1944 and 1945, the retests were done in the first two months of each academic year, and the results were therefore largely the effects of the preceding year. Although the significance of the class variation (24 per cent for the Class of 1941 and 47 per cent for the Class of 1937) remains speculative, the high level of these attack rates is noteworthy. If one assumes that the acquisition of the reactive state represents tuberculous infection, approximately 34 per cent of students became infected during medical school.

By means of the annual tuberculin test it was possible to determine an annual attack rate for each class. Although there was considerable variation from class to class, the average attack rates for each academic year showed surprisingly little variation. For the six classes 1940 through 1945, the rates were as follows: second-year test 12 per cent, third-year test 13 per cent, and fourth-year test 13 per cent (Table 10). The relation between this remarkable constancy in attack rate per year and the preponderance of pulmonary tuberculosis in the last two academic years is discussed below.

DISCUSSION

Pulmonary tuberculosis is the most serious medical problem that confronts the health departments of medical schools. Since the institution of an efficient case-finding program, the known incidence at the Harvard Medical School has been 2.2 per cent. Of special importance are cases with more than minor pulmonary lesions. Students with such major

6 are still in sanatoriums — 1 for six months and the other, now about to return to school, for twenty months. On the other hand, of the 13 cases in the major-lesion group, only 2 students did not require sanatorium care. Of the 11 who entered sanatoriums, 3 failed to return to medical school (after five, five and two years). The remaining 8 students spent from one to five years in sanatoriums before returning to medical school, averaging over thirty months of hospitalization (Table 3).

The minor lesions, however, were not so innocuous as these figures suggest. One student with a minor lesion developed a small new lesion shortly after returning to school following twelve months of sanatorium care. Also, at least 2 students with minor lesions considered not to require hospitaliza-

tion subsequently developed, during internship, re-activations severe enough to require sanatorium care.

No clear-cut correlation could be found between the severity of the lesion and the academic year of discovery or between the severity and the original tuberculin reaction (Tables 4 and 5).

On the other hand, correlation between severity of the lesion and method of detection was striking. Of the 31 cases in Classes 1936 to 1948 the method of detection is known in 25. Thirteen were found on routine chest x-ray examination, and 12 only after the appearance of suggestive symptoms. Of the former, 1 was classified as major and 12 as minor, and in the 12 detected on the basis of symptoms the distribution was directly reversed, 11 being major and 1 minor (Table 6). All 11 major cases

discovered on the appearance of symptoms occurred prior to the institution of the semiannual routine examinations, 5 students were tuberculin reactors on entrance, 5 were nonreactors, and 1 was not tested because of a known previous lesion. Four of the 5 reactors had negative chest films on entry

and were therefore subject only to voluntary annual examination before their fourth year. All 4 developed symptoms in their third year. By means

of the annual tuberculin retesting of negative reactors, it was possible to determine the interval between a previous negative reaction and the onset of symptoms. Of the 5 nonreactors in the annual retest who developed tuberculosis, 3 developed symptoms within a year (five, eleven and eleven months), 2 developed symptoms four and eleven months after the annual tuberculin test had shown a positive reaction.

The contrast between the results of the program of voluntary annual x-ray examination and those of the present compulsory annual and more recent semiannual examination is striking since the in-

stitution of the present program there have been 5 cases of pulmonary tuberculosis, 4 of which were detected by routine chest film and tuberculin test and 1 following a hemoptysis, all 5 students had minor lesions.

A breakdown of the 26 cases of known severity according to the program in force at the time of detection is given in Table 7. The elimination of the previously preponderant major cases under the present regime is noteworthy.

Tuberculin Test

Tuberculin tests on entrance showed an average of 51.7 per cent of students to be reactors (Table 8). A steep downward trend, leveling off or perhaps even reversing in recent years, presumably represents a lowering of tuberculous infection in the college-age population, associated with a decrease

dents remains a major medical problem. The incidence of significant active adult-type pulmonary tuberculosis in Harvard Medical School was 2.2 per cent.

Although the nature of the tuberculin reaction of medical students on entrance played no demonstrable role in the subsequent development of pulmonary tuberculosis, the conversion from the non-reactive to the reactive state while in medical school carried a liability greater than 5 per cent that the disease would develop before graduation.

Slightly over 30 per cent of students who entered Harvard Medical School as nonreactors became tuberculin reactors before graduation.

Although the number of cases of pulmonary tuberculosis discovered in the last two years of the medical-school course was four times as great as the number developing in the first two years, the incidence of acquisition of tuberculous infection was about the same (12 or 13 per cent annually) for each academic year. This constant annual attack rate suggests that factors other than opportunity for infection are responsible for the fourfold increase in cases of pulmonary tuberculosis during the term of clinical training.

The duration of disability caused by the pulmonary lesion was closely correlated with the severity of the lesion at the time of its discovery.

Lesions detected by the appearance of symptoms were of greater severity and carried a far greater period of disability than those discovered by any routine method.

The rapidity of progression of the disease in medical students is such that many lesions become symptomatically evident, and are thereby detected, in intervals between routine examinations made only annually.

The adoption of a program in which surveys are made at intervals more frequent than once a year led to the elimination of almost all symptom-detected cases and of all major lesions. It is our belief that a semiannual examination represents the maximum interval for routine re-examination by x-ray examination or tuberculin tests not only for medical students but also for nurses and interns.

lesions and virtually eliminated the cases detected on the basis of symptoms. Since the institution of the present program, there have been 5 cases of pulmonary tuberculosis, 4 of which were detected by the routine examination and 1 by the occurrence of hemoptysis. All 5 were minor lesions. If the asymptomatic cases had been allowed to continue until a later examination, or until the development of overt symptoms, it is not inconceivable that some students would have developed major lesions.

By means of the annual tuberculin test it was possible to determine the number of students who became infected each academic year. It was anticipated that more students would become tuberculin reactors during the clinical years, owing to greater exposure on the wards and in the autopsy room. Badger and Spink²¹ estimate that over 600 tuberculous patients are admitted annually to the general wards of one teaching hospital in Boston. At the same hospital 7 per cent of all autopsies performed up to 1941 showed active tuberculosis as a primary or contributing cause of

hours of physical and mental exertion. It must also be kept in mind that each academic year the medical student enters an age group whose mortality and estimated morbidity rate become increasingly high.²⁶ Unfortunately no adequate figures are available for the incidence of tuberculosis among carefully studied groups of the same age who are subject to the same conditions of living as well as to physical and mental exertion. As Rich²⁵ has emphasized in none of the published studies of graduate students in nonmedical fields are diagnostic criteria, thoroughness of study and duration of survey completely satisfactory. Only when adequate long-term surveys are made may one safely estimate the special risk of tuberculosis among medical students as contrasted with that among comparable groups of students not pursuing medical studies.

The lack of correlation between the nature of the original tuberculin reaction and the probability that active pulmonary tuberculosis will develop in medical school is of considerable interest. Experimentally it has been demonstrated that a previous infection

death.²² Heavy contamination of air near tables where fresh tuberculous tissue is examined has been repeatedly demonstrated.²³ In New York State 10 per cent of all deaths from tuberculosis occur in general hospitals,²⁴ and in Massachusetts, Dufault²² has estimated the figure at 20 per cent.

Despite greater opportunity for infection during the clinical years, an unexpected constancy in the attack rate (12 to 13 per cent) was found for each academic year. This uniformity indicates that there is equal opportunity for infection throughout each year. The predominance of cases of pulmonary tuberculosis in the third and fourth years has always been explained by greater exposure during those years. The constancy in annual attack rate seems to argue against greater exposure as the sole cause of the predominating number of cases during the clinical years; it is well known that factors other than opportunity for exposure operate in determining whether tuberculosis develops. A possible explanation is the accumulation of recently infected students whose primary lesions remain quiescent until clinical training is begun, when the lesions become reactivated because of the longer and irregular

offers some degree of protection against a subsequent infection under some conditions,^{25, 27} but offers undue susceptibility under others.^{28, 29} Furthermore, aside from such acquired resistance or hypersensitivity, it might be expected that fewer cases would appear among tuberculin reactors because this group has been challenged and has weathered the infection, whereas the nonreactor group has yet to demonstrate its native resistance. Such factors might be balanced by the possibility of endogenous recurrence in the reactor group. Reports in the literature on the incidence of tuberculosis in exposed groups of reactors and nonreactors vary from a greater incidence in the former^{30, 31} to a greater incidence in the latter,^{32, 33} or show no appreciable difference in the two groups. In the present study, the absence of appreciable difference between groups suggests that the nature of the original reaction presumably played only a minor role under the conditions studied.

SUMMARY AND CONCLUSIONS

The application of efficient case-detection methods shows that pulmonary tuberculosis in medical stu-

patient sought medical advice was nine months, and the total average delay for all cases before the diagnosis was established was seventeen months. There was a delay of from one to three months in 52 cases, including a few in which there was a delay of less than a month. There was an average delay of four to six months in 39 cases, of seven to twelve months in 48 cases, of thirteen to twenty-four months in 23 cases, of twenty-five to forty-eight months in 8 cases, of forty-nine to sixty months in 8 cases, and of sixty to one hundred and thirty-two months in 14 cases.

The relative culpability of patient and physician for the delay could not be established in all cases, but in 127 cases the patient was responsible for an average delay of nine months, and in 72 cases the blame for an average delay of seventeen months rested on the physician.

In 46 cases, or 24 per cent, the first x-ray examination failed to establish the diagnosis. A diagnosis of ulcer was rendered in 28 cases (14 per cent), with a resultant average delay of fourteen months before the final diagnosis was made, although 6 of these patients were operated on immediately. A diagnosis of ulcer with a question of cancer was made in 6 cases (3.1 per cent), with a resultant average delay of almost three months, although 3 of the 6 patients were operated on immediately. In 10 cases (5.2 per cent) a report of no disease was rendered, with a resultant delay of fifteen months. In 1 case a diagnosis of diverticulum of the stomach was made, and in another a diagnosis of gall-bladder disease. Both patients were subjected to immediate operation.

Study of the clinical histories in these cases revealed that epigastric pain or burning, epigastric distress or fullness and indigestion were the first symptoms in 131 (70 per cent) of the series. Anorexia occurred in 17 per cent, weakness or fatigue in 14 per cent, vomiting in 10 per cent, weight loss in 7 per cent, dysphagia in 6 per cent, and hemoemesis in 5 per cent.

In 17, or 8.8 per cent, a history of typical ulcer was given, and in 52 (27 per cent) a history suggestive of ulcer was obtained, making a total of 69, or 36 per cent, in which the ulcer syndrome was reproduced or suggested.

The implications of this analysis are clear. Apart from the failure of the patient to seek medical advice, a major source of error contributing to delay in establishing the diagnosis of cancer of the stomach is an astonishing degree of willingness on the part of physicians to treat, without x-ray examination or other investigation, patients in the cancer age group who have indigestion, epigastric pain or distress. From a study of the histories in these cases, it seems clear that patients whose symptoms were suggestive of ulcer were treated on that basis, and that those whose symptoms were so indefinite as to suggest insignificant functional disorders were

treated by various forms of dietotherapy and usually with alkaline powders. This casual method of dealing with such complaints has become widely known to the public and, in combination with advertisements for patent remedies, is undoubtedly a factor in the high incidence of self-treatment.

There is obviously a great lack of appreciation of the serious import of such symptoms in persons past the age of forty-five, and insufficient familiarity with the frequency with which such symptoms herald the presence of cancer, on a purely statistical basis.

Rivers,⁷ in a significant paper, has emphasized the fact that indigestion occurring in patients over forty-five years of age is frequently due to cancer. In an analysis of 2448 patients in various age groups who presented themselves with the symptom of indigestion, cancer of the stomach was found to be the cause in 8.8 per cent of patients from forty-five to forty-nine, in 10.8 per cent of those from fifty-five to fifty-nine, in 24 per cent of those from sixty to sixty-four, and in 36 per cent of those over seventy.

It is difficult to believe that anyone familiar with these figures would be willing to risk treatment of a patient with dyspepsia without benefit of searching investigation. It is essential that this information be disseminated, and it is necessary to reiterate that dyspepsia in patients over forty-five is a grave symptom.

Another source of error is an exaggerated notion regarding the accuracy of roentgenologic diagnosis. It is often stated that intragastric lesions can be accurately diagnosed in 90 to 95 per cent of cases. On inquiry, however, it seems clear that this high degree of accuracy is attainable only in large centers, where roentgenologists of exceptional experience and skill are available, and even then only when questionable cases are subjected to repeated examinations. This is not to decry the great value of roentgenographic diagnosis, but it is essential to point out that, in the hands of the average roentgenologist, such accuracy in diagnosis is not approached. In this series there were wrong diagnoses in 24 per cent, and Engel⁸ has stated that in this type of examination there is an admitted error of 20 to 25 per cent. In any patient in whom the diagnosis of gastric cancer is suggested, repeated x-ray examination at short intervals is imperative if the patient's symptoms persist.

The differential diagnosis of gastric ulcer and ulcerating gastric cancer merits special consideration. In fact the whole question of the management of gastric ulcer needs to be reviewed. A growing body of evidence suggests that there is an irreducible error in the neighborhood of 10 to 14 per cent in the roentgenologic diagnosis of this disease. Kirklin,⁹ emphasizing a point that is obviously not appreciated by the average clinician, writes as follows:

DYSPEPSIA, ULCER AND GASTRIC CANCER*

THOMAS J. ANGLEM, M.D.†

BROOKLINE, MASSACHUSETTS

IN 1928 Sir Berkeley Moynihan¹ wrote, "Not a little of the incredulity of patients and the apathy of medical men is based upon the undisputed conviction that cancer of the stomach is incurable." When it is realized that under the favorable circumstances existing in large metropolitan hospitals only 5 of every 100 patients who apply for treatment are cured of their disease, this becomes understandable, perhaps, but is still not justifiable. It is an undoubted fact that most practitioners of medicine have never seen a cured case of gastric cancer but that they have seen large numbers of patients die of the disease. When one recalls that this disease accounts for a third of all deaths from cancer, numbering approximately 40,000 cases yearly in this country, no further argument regarding its importance appears to be necessary.

The insidious character of gastric cancer is often put forward as the reason for this pessimistic picture, and although it is unquestionably true that in a small percentage of patients the disease is beyond the possibility of surgical extirpation when the first symptom manifests itself, study of the clinical histories reveals that in most cases symptoms have been present for months or years before the diagnosis is established. The culpability for this delay in establishing the diagnosis rests not only on the patient who fails to seek medical advice during the early stages of the disease but also in large measure on the physician who is satisfied to treat the patient medically for months or years without benefit of the searching investigation that is imperative in all such cases.

As Mullen² has pointed out

It is an unfortunate fact that most persons consider a mild degree of gastric discomfort to be a normal part of the process of growing older, and the words "indigestion" and "dyspepsia" to most minds signify an uncomfortable but entirely benign process. Yet within these two words lies the whole story of early gastric cancer symptomatology.

It is also true that this attitude is shared in large measure by many physicians.

The significant factor that is clearly responsible for the delay in the diagnosis of gastric cancer is the unfortunate circumstance that early cancer of the stomach shares with benign gastric lesions and functional disorders the symptoms of dyspepsia or indigestion as an early manifestation. This dyspepsia may be indefinite, or may simulate to a slight or marked degree or may mimic exactly the syndrome associated with benign peptic ulcer. The

resemblance of gastric cancer to the classic ulcer syndrome has been general knowledge for many years. In 1906 Graham³ wrote as follows: "In the later nineties our attention was strongly attracted by the many long histories of 'dyspeptic trouble' that preceded cancer of the stomach, and the thought that ulcer was this precancerous condition became firmly implanted." In 1909 Moynihan⁴ reported that 2 of every 3 patients with cancer of the stomach on whom he had operated had had a previous history of ulcer. Despite the fact that these observations were made forty to fifty years ago, their implications have not been widely appreciated or seen in proper perspective in relation to their obvious bearing on early diagnosis. The more recent literature continues to emphasize the frequency of ulcer or symptoms of ulcer in the clinical histories of patients with cancer of the stomach. Blackford⁵ reported that 38 per cent of his patients presented histories of preceding ulcer, and Eusterman⁶ stated that in 47 per cent of proved cases of gastric cancer encountered at the Mayo Clinic, the history was that of the accepted syndrome of benign ulcer. Whether the natural course of the disease in these cases is a degeneration of a previously benign ulcer or peptic ulceration of a slowly growing cancer or a prolonged precancerous state, distinct from ulcer, is a matter of secondary importance. The significant point is that in a substantial percentage of cases a long history exactly mimics or closely resembles the accepted syndrome of ulcer.

The present study is based on the records of 192 patients with carcinoma of the stomach seen in private practice and at the Massachusetts Memorial Hospitals. Since the majority of these patients were referred for consideration of surgical treatment, these cases represent a selected series, and this fact is reflected in a somewhat higher resectability rate than is usually reported. Seventy-seven cases were suitable for resection—a rate of 41 per cent. Twenty of these, however, were palliative resections, and 57 were resections for cure—in the latter group, the resectability rate was 30 per cent. Thirty-three cases were classed as inoperable, 60 were found to be inoperable on exploration, 18 were suitable for palliative procedures only, and 20 were suitable for palliative resections, 4 patients refused operation. Thus, in a relatively favorable, somewhat selected series of 188 patients in whom the ultimate status was determined, 111 (70 per cent) were hopeless when first seen by the surgeon.

Long delay before the diagnosis was established was almost the rule. The average delay before the

†Assistant professor of surgery, Boston University School of Medicine.

* * *

Large numbers of patients with gastric cancer have lost their lives because their disease was confused with benign ulcer. A more aggressive approach to the problem of gastric ulcer should result in the salvage of many such patients.

VAGINAL URETERAL ORIFICES*

WINTHROP M. FLAGG, M.D.†

BURLINGTON, VERMONT

TRUE supernumerary kidney is a rare anomaly.¹ In a review of the literature Headings and Palmer² found a total of 44 cases, of which 6 had extravascular ureteral orifices. A case reported by Shane³ and the following case bring the total number of cases of supernumerary kidney with a vaginal orifice to 8.

A. G., a 7-year-old girl, was seen because of urinary incontinence, which had been present since birth but was apparent only when the child was on her feet. There had been no nocturnal enuresis since the age of 2. With the patient in the supine position there was no evidence of urinary leakage, but examination when she was standing revealed an intermittent spurring of urine from what appeared to be a ureteral orifice in the vestibule of the vagina. Intravenous urography (Fig. 1) showed a supernumerary kidney on the left, located above a normal-functioning left kidney. A ureteral catheter introduced into the vaginal orifice ascended to the pelvis of the upper left kidney. Ureteronephrectomy disclosed a true case of supernumerary kidney. Convalescence was uneventful and was not followed by urinary leakage since. It should be pointed out that this child had been examined by several physicians, but always in the supine position, and that the family had been continuously reassured that she would outgrow this disability.

In 1937 Eisendrath and Rolnick⁴ found in the literature 88 cases in which the ureter opened in the vaginal vestibule and 55 cases with opening into the vault of the vagina or the uterus. Since then, 6 cases⁵⁻⁷ have been reported, bringing the total to 61.

D. C., a 35-year-old housewife, was admitted to the hospital complaining of lifelong incontinence of urine. The amount, although not excessive, was sufficient to require the wearing of a vulva pad at all times. The patient had been married for 7 years but had no children, a finding that is not unusual in cases of vaginal urinary leakage.

Physical examination was negative, except for urinary leakage from the vault of the vagina (not from the urethra).

FIGURE 1 Case 1. The intravenous urogram shows a supernumerary left kidney with a vaginal ureteral orifice.

Laboratory study revealed normal findings. Intravenous urograms (Fig. 2) showed a normal right kidney, but no

Such ulcers designated as benign, without qualifying adjectives are designated so — but with the implication that as no marks of malignancy are discerned, the lesions are probably benign, although malignancy cannot be positively excluded. The fact that 10 per cent or more of gastric ulcers are found microscopically to be malignant has been publicized thoroughly, and the roentgenologist feels that his diagnosis may not have been misleading, for he assumes that every ulcer will be considered as potentially malignant until proved innocent.

It is undoubtedly on the basis of this apparently irreducible error in roentgenologic interpretation that Allen and Welch¹⁰ found carcinoma in fourteen per cent of 277 cases diagnosed as ulcer. Judd and Priestley,¹¹ in a similar series of 237 cases in which a diagnosis of benign gastric ulcer was made, found cancer on exploration in 19 (8 per cent) and in 146 cases diagnosed as benign ulcers that were treated medically, 10 per cent of patients subsequently developed gastric cancer. The wisdom of treating medically any lesion that carries a 10 to 14 per cent chance of being malignant seems open to serious question. The approach of Judd and Priestley¹¹ in evaluating the relative risks attending medical versus surgical treatment for lesions diagnosed as gastric ulcer seems to go far toward clarifying this sharply debated subject. In a further analysis of 146 cases treated medically, they found that only 47 per cent of patients considered themselves cured, an additional 16 per cent had no symptoms if the medical regime was followed constantly, 5 per cent had gastric ulcer on x-ray examination, 11 per cent were operated on because of failure of medical treatment and had ulcer, and 10 per cent (14 patients) presented definite evidence of cancer. Of these, 7 died of metastatic cancer, the remainder were explored surgically, and in only 3 could the cancer be removed. In contrast, of 162 patients with gastric ulcer treated surgically who were followed for from one to five years, only 1 classified the result as unsatisfactory.

In the past few years there have been increasing reports of large series of gastric resection for benign ulcers of the stomach and duodenum, with mortality rates well under 5 per cent. Counsellor, Waugh and Claggett,¹² Judd and Priestley,¹¹ Jordan and Lahey,¹³ and St. John¹⁴ reported rates of 1.3, 2.5, 2.7 and 3 per cent respectively, and McKittrick, Moore and Warren¹⁵ reported a series of 94 cases without a death.

If one assumes that the results of surgical treatment are at least as good as those of medical treatment, with an operative mortality of 3 to 4 per cent, and balances against this the facts that with medical treatment 10 to 14 per cent of patients develop cancer and that a significant percentage have perforations and serious hemorrhages, — some of whom die, — it seems difficult to escape the conclusion that gastric ulcer, at least in patients over the age of forty-five or fifty, should be considered primarily a surgical problem. Of course each case is an individual problem, and exceptions should be made in patients who, because of advanced age,

obesity or coexisting disease, must be regarded as poor surgical risks. Certainly, a more radical attitude toward this disease will yield a significant increase in the percentage of cured gastric cancer, for Allen and Welch¹⁰ have shown that the cure rate for cancers encountered in operation on supposed ulcers is double the prevailing rate. The advantages resulting from the greater use of surgery in dealing with ulcerating gastric lesions, of course, depend on the maintenance of a low operative mortality. Rates such as those cited above can be expected only in the hands of experienced gastric surgeons.

In a certain percentage of ulcerating gastric lesions, the roentgenologist makes a diagnosis of gastric ulcer but suggests that cancer cannot be ruled out. In such cases the patient is frequently subjected to a therapeutic trial on medical treatment, the clinical response being observed, the stools watched for the presence or absence of occult blood, and after an interval of two or three weeks the change in the roentgenographic picture noted. This method of management is advocated by most gastroenterologists, including Jordan¹⁴ and Eusterman,¹⁷ who states that the results of medical treatment are only slightly less decisive than those of operation and histologic examination in establishing the diagnosis of ulcer or cancer. My experience with therapeutic trial, as well as that of many others, does not support this belief. Ulcerating cancers often respond so favorably — both clinically and in the rapid diminution of the size of the ulcer — as to lead one to the conviction that the lesion was benign. At best, when the result of therapeutic trial suggests that the lesion is malignant and operation is advised, a delay of from four to six weeks or longer is frequent.

The chief objection to the therapeutic method, however, is that the end results do not bear out the contention of those who advocate it. Eusterman¹⁷ reports the development of cancer in 10 per cent of medically treated ulcer cases not limited to patients in the cancer age or to patients in whom the suspicion of cancer is greater than average.

To one accustomed to dealing with cancer, a diagnostic method that depends for its success on observing the continued growth or persistence of a malignant tumor, in spite of treatment for weeks, has little to recommend it, such a procedure may have been amply justified when gastric resection carried an operative mortality of from 15 to 20 per cent, but with a mortality in the neighborhood of 3 per cent, the risk of medical treatment of a malignant tumor must be carefully weighed.

A hopeful fact is that much of the delay in the diagnosis of gastric cancer is susceptible of correction. It is obvious that the grave significance of dyspepsia occurring after forty-five must be stressed persistently in undergraduate and postgraduate medical teaching, and that the public must also be made aware of this hazard.

THE USE OF STREPTOMYCIN IN COLON-BACILLUS PERITONITIS*

Report of a Case

S RICHARD MUELLNER, M D,† AND ALEXANDER RUTENBERG, M D ‡

BOSTON

THE recorded clinical experience with streptomycin is as yet quite meager. The technic of administering this drug and the dosage to be employed in infections with various bacteria have not yet been established. The variation in susceptibility of different strains of the same bacteria and the rapid development of fastness in experiments in vitro suggest that a clinical evaluation of these factors is desirable.¹⁻³ The pooling of clinical experience

coli on smear and culture. The urine from the right kidney was sterile. An attempt was made to expedite the passage of the ureteral stone by dilatation of the ureter through cystoscopic means. Four days later however, the patient had sharp left-flank pain, chills and high fever, which proved to be due to the sudden passage of the stone from the calyx into the upper fifth of the ureter, the infection being thus bottled up in the left kidney. An immediate ureterolithotomy was done. At operation the retroperitoneal tissues were edematous, and the ureter was swollen. The ureter was incised over the stone and after the stone was extracted, thick green pus which contained *Esch coli* on culture, drained from the

with streptomycin in carefully studied cases therefore seems to be worthwhile. It is with this purpose in mind that the following report is presented

CASE REPORT

W S (BIH 67286), a 50-year-old man, was admitted to the hospital because of pain in the left flank of 3 months' duration, associated at its onset in July, 1945, with chills and fever. Urologic investigation revealed a stone in the lower calyx of the left kidney and another stone at the left ureterovesical junction. The urine from the left kidney and from the bladder was full of pus and contained *Escherichia*

kidney. Following this operation the patient made an uneventful recovery.

It then became necessary to remove the stone at the ureterovesical junction, to prevent the establishment of a permanent ureteral fistula as a result of the previous ureterolithotomy. Consequently, 12 days later, the lower left ureter was exposed through a Gibson incision. In this region the retroperitoneal tissues were also edematous. The peritoneum itself, however, was extremely thin. Despite gentle retraction 2 small holes were inadvertently made in the peritoneum. These were at once closed by suture. The ureter was then incised, the stone was extracted, and the wound was closed around a drain.

The postoperative course was stormy. The patient developed unmistakable signs of peritonitis with paralytic ileus—a rather infrequent complication after this type of surgery. A peritoneal tap revealed cloudy fluid containing pus and *Esch coli* on smear and culture. Despite intubation of the small bowel by a Miller-Abbott tube, adequate chemotherapy with penicillin and sulfonamides, parenteral fluids

function was apparent on the left side. The left lateral wall and dome of the bladder were deformed by extrinsic pressure. A pelvic left kidney was immediately suspected. Gynecologic examination revealed a moderate-sized fibroid uterus, but no mass could be identified as kidney. The ureteral opening in the vagina was found deep in the vault and on the anterior wall. With much difficulty a No. 5 Fr ureteral catheter could be passed about 15 cm. Skiodan was injected and ascended to about the level of the bladder deformity (Fig. 3). This seemed to confirm the tentative diagnosis of pelvic kidney, and a low-left-rectus incision was accordingly made, the left ureter being easily picked up. Dissection was carried down to the vagina and up as far as possible with this type of incision, no kidney was encountered. The peritoneal cavity was opened to permit better palpation of the abdomen. The right kidney was normal, but the left kidney fossa was empty. The bladder deformity was found to be due to the fibroid uterus. A diagnosis of aplastic left kidney was made, and about 8 cm. of the distal ureter was removed after double ligation with black silk. The proximal end was transplanted through the rectus fascia, so that if hydronephrosis developed, the ureter could be readily picked up and catheterized, and the location and character of the kidney determined prior to ne-

In the cases reported above, careful attention to the case history and scrupulous inspection were sufficient to lead to the correct diagnosis.

FIGURE 2 Case 2 The intravenous urogram shows a normal right kidney, no apparent function on the left and deformity of the left side of the bladder

phrectomy. This was never necessary. Six months after operation the patient was well, and for the first time since birth there was no urinary leakage.

FIGURE 3 Case 2 This film shows the left ureter following the injection of skiodan into the vaginal ureteral orifice

SUMMARY

One case of supernumerary kidney with a vaginal ureteral orifice is described, and one of an anomalous ureteral opening in the vaginal vault, making the total numbers of such cases reported 8 and 61, respectively.

Epidemiological Board³³² Over 6000 ASTP students in widely scattered parts of the United States received one dose of 1.0 cc of a bivalent anti-A and anti-B vaccine prepared by concentration of the virus in infected chorioallantoic fluid, inactivated with formalin. An equal number of subjects served as controls. Influenza A in epidemic form appeared in each group at varying intervals, from twelve days before to five and a half weeks after vaccination was undertaken. Taken as a whole, the observed incidence of influenza among the inoculated was only 31 per cent of that in the controls (morbidity rates of 2.22 as against 7.11 per cent). The ratio of cases in inoculated subjects and controls varied greatly in individual groups, however, from a high of 1.60 (1.15 vs. 6.93 per cent morbidity) to a low of 1.15 (5.25 vs. 7.88 per cent). Best results were obtained when exposure to infection occurred a few weeks after vaccination, and at least a week's interval was necessary before any protection was evident. The poorest results were observed in the group experiencing the longest interval between vaccination and exposure to infection, but it is not entirely clear whether the relative failure in this group was due to the long interval or to other factors. Detailed reports of these studies present evidence that a multitude of factors determine the results to be expected following vaccination³³³⁻³³⁹. The conclusions to be drawn appear to be that immunization, with the vaccine employed, afforded a better than a three to one chance of protection, for a period of a few months, against the two most prevalent strains of influenza. A subsequent study, employing the same vaccine, indicated that protection may persist for as much as a year.³⁴⁰ Furthermore, in this study and another more recently reported,³⁴¹ the incidence of influenza among vaccinated subjects was from one fifth³⁴⁰ to one tenth³⁴¹ that in the controls. If these results can be confirmed, there will be a far more satisfactory basis for justifying the clinical use of the vaccine than has heretofore existed. Mass vaccination in the armed forces was wholly justifiable not only for the protection of large bodies of redeploying troops but also as a means of controlling what would have been an unparalleled opportunity for rapid and extensive spread of the disease if an epidemic had arisen. At present there is no apparent justification for widespread or routine use of the vaccine, in the absence of a clearly defined epidemic of influenza A or B. When a definite risk of exposure to either type of influenza exists, however, the vaccine may be used to protect persons whose circumstances warrant a special effort to prevent sudden illness, such as during the conduct of important personal or professional affairs and during travel. If the vaccine proves effective for as long as a year, its use on a large scale in the civilian population may deserve consideration — in the autumn of years that seem to be scheduled

for one of the periodic outbreaks characteristic of influenza in its present form. The recent experimental infection studies of Henle et al.³⁴² throw an interesting light on the possible results to be expected from periodic reimmunization with influenza, suggesting that primary and accelerated reactions, analogous to the different vaccination reactions associated with varying degrees of resistance to smallpox, may be observed.

The essentially localized nature of the lesions of influenza has led to some skepticism regarding the results that may be expected from any parenteral route of immunization. It is on this basis that various investigators have attempted to immunize by inhalation of modified virus.³⁴¹⁻³⁴³ Burnet et al.³⁴³ and Francis³⁴⁴ have shown that a factor in nasal secretions is capable of inactivating influenza virus, and it has been demonstrated that this mechanism is enhanced by parenteral immunization.³⁴⁵ It is fair to assume, therefore, that the production of an effective local resistance will be related to the production of a sufficiently high systemic level of immunity, but the surprisingly frequent finding of clinical influenza in persons exhibiting high antibody titers against the infecting virus has not yet been explained.

Local and constitutional reactions following administration of influenza vaccine have been widely observed, and are reported as occurring in from less than 1%³⁴⁴ to 59 per cent³⁴⁹ of different groups. These extreme differences apparently depend both on the definition of a reaction and on the pains taken to obtain reports. Constitutional reactions have been sufficiently frequent and severe, at all events, to indicate the need for modifications in either the product or the dosage schedule, or both. The possibility that divided doses increase the efficacy of the vaccine has been suggested by animal experiments,³⁴⁶ and would be expected on a theoretical basis. Antibody titrations on human subjects, however, have not borne this assumption out.³⁴⁷⁻³⁴⁷ In fact, Hare³⁴⁸ has suggested that secondary antibody responses from repeated doses of influenza vaccine are not to be expected, since the first injection is in all probability actually a booster dose for the great majority of subjects.

Several considerations warrant a conservative attitude toward the use of influenza vaccine, even if improvements in the vaccine should lead to a higher degree of protection over longer periods. Foremost among these is the possibility that sensitivity to the egg proteins in the vaccine will induce severe reactions. Among the 6000 ASTP students inoculated in the study referred to above, an asthmatic reaction occurred in only 1 case³⁴⁶ and an urticarial reaction in 1.³⁴⁸ At least one fatal reaction has been observed, however, following the use of a vaccine prepared from hen's eggs,³⁴⁹ and such reactions may be anticipated more frequently in persons receiving repeated booster injections of a vac-

and transfusions of blood, the clinical status became progressively worse. The patient remained distended, toxic and irrational. On the 15th postoperative day, when the patient's condition was most desperate, streptomycin was obtained, during the first 3 days 2,000,000 units were administered daily by constant intravenous drip, and the patient was given 500,000 units intramuscularly every 6 hours for 4 more days.

The effect of this therapy was most dramatic (Fig. 1). The temperature and pulse rate dropped at once, and the patient became rational. The abdominal distention receded, and the patient took nourishment and passed normal stools. The peritonitis seemed to have been completely eliminated by streptomycin. The urine, on the other hand, became sterile and free from pus for only 2 days after the initiation of the streptomycin therapy. Thereafter, despite the daily administration of 2,000,000 units of this drug for a total of 7 days, pus and *Esch. coli* continued to be present in the urinary sediment.

A few points in this case history are worthy of comment. The patient was rapidly failing because of a severe colon-bacillus peritonitis, which was uninfluenced by any of the sulfonamides. A fatal outcome was unquestionably prevented by the use of streptomycin. It is interesting that although the bacilli were apparently completely eliminated from the peritoneal cavity, permanent sterilization of the urinary tract was not achieved, despite the fact that the urinary tract was free from obstruction. The reason for this discrepancy is not clear. Experiments in vitro have demonstrated that bacteria
